http://comp322.rice.edu

Formalizing Parallel Prefix: Scan operations

- The *i-scan* operation is an inclusive parallel prefix sum operation.

- The scan operator was introduced in APL in the 1960's, and has been popularized recently in more modern languages, most notably the NESL project in CMU

Formalizing Parallel Prefix: Scan operations

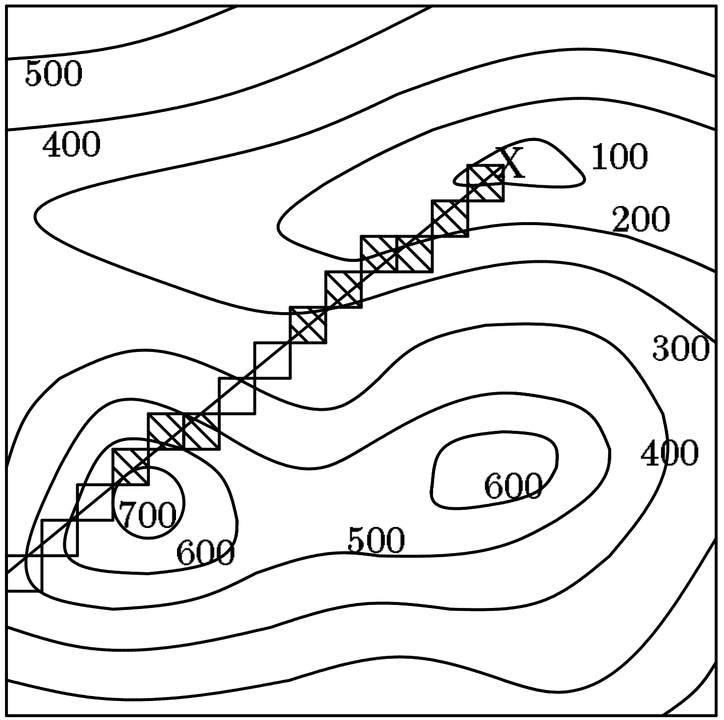
- The *e-scan* operation is an exclusive parallel prefix sum operation. It takes a binary associative operator $\oplus$ with identity I, and a vector of n elements, $[a_0, a_1, ..., a_{n-1}]$, and returns the vector $[I, a_0, (a_0 \oplus a_1), ..., (a_0 \oplus a_1 \oplus \ldots \oplus a_{n-2})]$.

- An e-scan can be generated from a i-scan by shifting the vector right by one and inserting the identity. Similarly, the i-scan can be generated from the e-scan by shifting left, and inserting at the end the sum of the last element of the e-scan and the last element of the original vector.

Line-of-Sight Problem

- Problem Statement: given a terrain map in the form of a grid of altitudes and an observation point, X, on the grid, find which points are visible along a ray originating at the observation point. Note that a point on a ray is visible if and only if no other point between it and the observation point has a greater vertical angle.

- Define angle[i] = angle of point i on ray relative to observation point, X (can be computed from altitudes of X and i)
- A max-prescan on angle[*] returns to each point the maximum previous angle.
- Each point can compare its angle with its max-prescan value to determine if it will be visible or not



Segmented Inclusive Scan

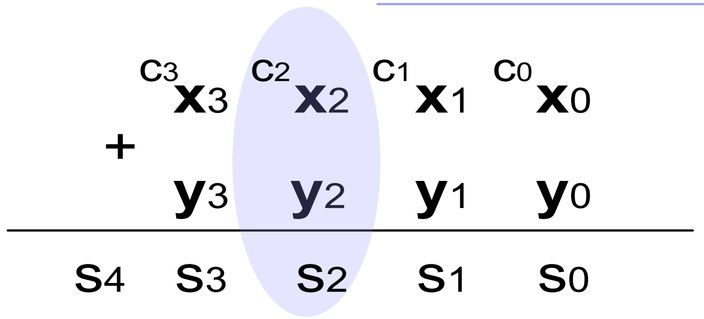
Goal: Given a data vector and a flag vector as inputs, compute independent i-scans on segments of the data vector specified by the flag vector.

$$x_i = \begin{cases} a_0 & i = 0 \\ \begin{cases} a_i & f_i = 1 \\ (x_{i-1} \oplus a_i) & f_i = 0 \end{cases} & 0 < i < n \end{cases}$$

a	$=$	[5	1	3	4	3	9	2	6]
f	$=$	[1	0	1	0	0	0	1	0]
segmented +-scan	$=$	[5	6	3	7	10	19	2	8]
segmented max-scan	$=$	[5	5	3	4	4	9	2	6]

Binary Addition

This is the pen and paper addition of two 4-bit binary numbers **x** and **y**.
c represents the generated carries.
s represents the produced sum bits.



A **stage** of the addition is the set of **x** and **y** bits being used to produce the appropriate sum and carry bits. For example the highlighted bits x_2, y_2 constitute **stage 2** which generates carry c_2 and sum s_2 .

Each stage *i* adds bits a_i, b_i, c_{i-1} and produces bits s_i, c_i
The following hold:

a_i	b_i	c_i	Comment:	Formal definition:
0	0	0	The stage “kills” an incoming carry.	“Kill” bit: $k_i = \overline{x_i + y_i}$
0	1	c_{i-1}	The stage “propagates” an incoming carry	“Propagate” bit: $p_i = x_i \oplus y_i$
1	0	c_{i-1}	The stage “propagates” an incoming carry	
1	1	1	The stage “generates” a carry out	“Generate” bit: $g_i = x_i \bullet y_i$

Binary Addition

a_i	b_i	c_i	Comment:	Formal definition:
0	0	0	The stage “kills” an incoming carry.	“Kill” bit: $k_i = \overline{x_i + y_i}$
0	1	c_{i-1}	The stage “propagates” an incoming carry	“Propagate” bit: $p_i = x_i \oplus y_i$
1	0	c_{i-1}	The stage “propagates” an incoming carry	
1	1	1	The stage “generates” a carry out	“Generate” bit: $g_i = x_i \bullet y_i$

The carry c_i generated by a stage *i* is given by the equation:

$$c_i = g_i + p_i \cdot c_{i-1} = x_i \cdot y_i + \left(x_i \oplus y_i\right) \cdot c_{i-1}$$

This equation can be simplified to:

$$c_i = x_i \cdot y_i + \left(x_i + y_i\right) \cdot c_{i-1} = g_i + a_i \cdot c_{i-1}$$

The “a_i” term in the equation being the “alive” bit.
The later form of the equation uses an OR gate instead of an XOR which is a more efficient gate when implemented in CMOS technology. Note that:

$$a_i = \overline{k_i}$$

Where k_i is the “kill” bit defined in the table above.

Binary addition as a prefix sum problem.

- We define a new operator: “ ∘ ”
- Input is a vector of pairs of ‘propagate’ and ‘generate’ bits:

$$(g_n, p_n)(g_{n-1}, p_{n-1})\ldots(g_0, p_0)$$

- Output is a new vector of pairs:

$$(G_n, P_n)(G_{n-1}, P_{n-1})\ldots(G_0, P_0)$$

- Each pair of the output vector is calculated by the following definition:

$$(G_i, P_i) = (g_i, p_i) \circ (G_{i-1}, P_{i-1})$$

$$Where:$$

$$(G_0, P_0) = (g_0, p_0)$$

$$(g_x, p_x) \circ (g_y, p_y) = (g_x + p_x \cdot g_y, p_x \cdot p_y)$$

$$with \quad +,\cdot \quad being\ the\ OR, AND\ operations$$

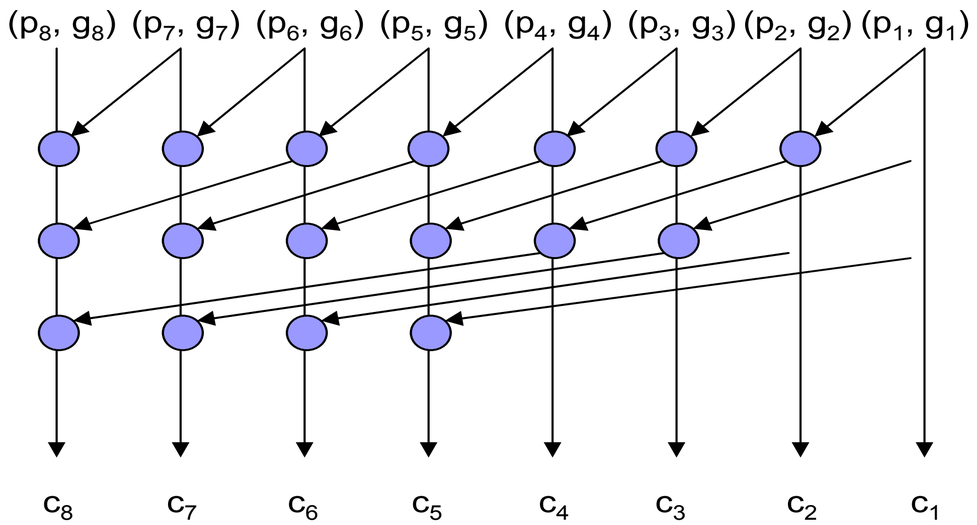
1973: Kogge-Stone adder

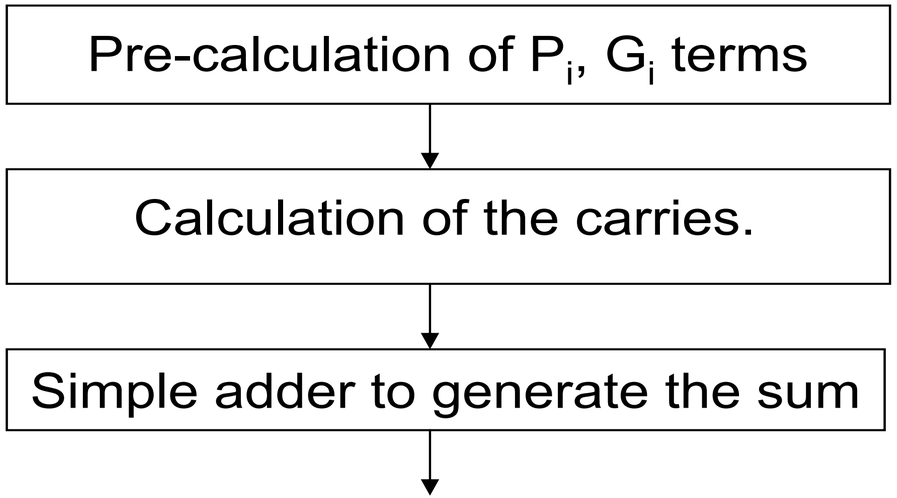


- The Kogge-Stone adder has:
  - Low depth
  - High node count (implies more area).
  - Minimal fan-out of 1 at each node (implies faster performance).

Slide acknowledgment: Kostas Vitoroulis, Concordia University

Summary

- A parallel prefix adder can be seen as a 3-stage process:



- There exist various architectures for the carry calculation part.
- Trade-offs in these architectures involve the
  - area of the adder
  - its depth
  - the fan-out of the nodes
  - the overall wiring network.
