0 Course Organization

The desired learning outcomes from the course fall into three major areas, that we refer to as modules:

- **Module 1: Parallelism** — creation and coordination of parallelism (async, finish), abstract performance metrics (work, critical paths), Amdahl’s Law, weak vs. strong scaling, data races and determinism, data race avoidance (immutability, futures, accumulators, dataflow), deadlock avoidance, abstract vs. real performance (granularity, scalability), collective and point-to-point synchronization (phasers, barriers), parallel algorithms, systolic algorithms.

- **Module 2: Concurrency** — critical sections, atomicity, isolation, high level data races, nondeterminism, linearizability, liveness/progress guarantees, actors, request-response parallelism, Java Concurrency, locks, condition variables, semaphores, memory consistency models.

- **Module 3: Locality and Distribution** — memory hierarchies, locality, cache affinity, data movement, message-passing (MPI), communication overheads (bandwidth, latency), MapReduce.

Each module is further divided into units, and each unit consists of a set of topics. This document consists of lecture notes for Module 1. The section numbering in the document follows the unit.topic format. Thus, Section 1.2 in the document covers topic 2 in unit 1. The same numbering convention is used for the videos hosted in Canvas.

1 Task-level Parallelism

1.1 Task Creation and Termination (Async, Finish)

To introduce you to a concrete example of parallel programming, let us first consider the following sequential algorithm for computing the sum of the elements of an array of numbers, $X$:

**Algorithm 1: Sequential ArraySum**

| Input: Array of numbers, $X$. |
| Output: \textbf{sum} = sum of elements in array $X$. |

\[ \text{sum} \leftarrow 0; \]

\[ \text{for } i \leftarrow 0 \text{ to } X.length - 1 \text{ do} \]
\[ \quad \text{sum} \leftarrow \text{sum} + X[i]; \]

\[ \text{return sum}; \]

This algorithm is simple to understand since it sums the elements of $X$ sequentially from left to right. However, we could have obtained the same algebraic result by summing the elements from right to left instead. This over-specification of the ordering of operations in sequential programs has been classically referred to as the Von Neumann bottleneck \[2\]. The left-to-right evaluation order in Algorithm 1 can be seen in the computation graph shown in Figure 1. We will study computation graphs formally later in the course. For now, think of each node or vertex (denoted by a circle) as an operation in the program and each edge (denoted by an arrow) as an ordering constraint between the operations that it connects, due to the flow of the output from the first operation to the input of the second operation. It is easy to see that the computation graph in Figure 1 is sequential because the edges enforce a linear order among all nodes in the graph.

How can we go about converting Algorithm 1 to a parallel program? The answer depends on the parallel programming constructs that are available for our use. We will start by learning task-parallel constructs. To
understand the concept of tasks informally, let’s use the word, task, to denote a sequential subcomputation of a parallel program. A task can be made as small or as large as needed e.g., it can be a single statement or can span multiple procedure calls. Program execution is assumed to start as a single “main program” task, but tasks can create new tasks leading to a tree of tasks defined by parent-child relations arising from task creation, in which the main program task is the root. In addition to task creation, we will also need a construct for task termination, i.e., a construct that can enable certain computations to wait until certain other tasks have terminated. With these goals in mind, we introduce two fundamental constructs for task parallelism, async and finish, in the following sections.

1.1.1 Async notation for Task Creation

The first parallel programming construct that we will learn is called async. In pseudocode notation, “async ⟨stmt⟩”, causes the parent task (i.e., the task executing the async statement to create a new child task to execute the body of the async, ⟨stmt⟩, asynchronously (i.e., before, after, or in parallel) with the remainder of the parent task. The notation, ⟨stmt⟩, refers to any legal program statement e.g., if-then-else, for-loop, method call, or a block enclosed in { } braces. (The use of angle brackets in “⟨stmt⟩” follows a standard notational convention to denote units of a program. They are unrelated to the < and > comparison operators used in many programming languages.) Figure 2 illustrates this concept by showing a code schema in which the parent task, T₀, uses an async construct to create a child task T₁. Thus, STMT1 in task T₁ can potentially execute in parallel with STMT2 in task T₀.

async is a powerful primitive because it can be used to enable any statement to execute as a parallel task, including for-loop iterations and method calls. Listing 1 shows some example usages of async. These examples are illustrative of logical parallelism, since it may not be efficient to create separate tasks for all the parallelism created in these examples. Later in the course, you will learn the impact of overheads in determining what subset of logical parallelism can be useful for a given platform.

2 These constructs have some similarities to the “fork” and “join” constructs available in many languages, including Java’s ForkJoin framework (which we will learn later in the course), but there are notable differences.
// Example 1: execute iterations of a counted for loop in parallel
// (we will later see forall loops as a shorthand for this common case)
for (int ii = 0; ii < A.length; ii++) {
    final int i = ii; // i is a final variable
    async { A[i] = B[i] + C[i]; } // value of i is copied on entry to async
}

// Example 2: execute iterations of a while loop in parallel
pp = first;
while (pp != null) {
    T p = pp; // p is an effectively final variable
    async { p.x = p.y + p.z; } // value of p is copied on entry to async
    pp = pp.next;
}

// Example 3: Example 2 rewritten as a recursive method
static void process(T p) { // parameter p is an effectively final variable
    if (p != null) {
        async { p.x = p.y + p.z; } // value of p is copied on entry to async
        process(p.next);
    }
}

// Example 4: execute method calls in parallel
async { left_s = quickSort(left); }
async { right_s = quickSort(right); }

Listing 1: Example usages of async

All algorithm and programming examples in the module handouts should be treated as “pseudocode”, since they are written for human readability with notations that are more abstract than the actual APIs that you will use for the programming projects in COMP 322.

In Example 1 in Listing 1 the for loop sequentially increments index variable i, but all instances of the loop body can logically execute in parallel because of the async statement. The pattern of parallelizing counted for-loops in Example 1 occurs so commonly in practice that many parallel languages include a specialized construct for this case, that may be given a name such as foreach, forall or forasync.

In Example 2 in Listing 1 the async is used to parallelize computations in the body of a pointer-chasing while loop. Though the sequence of p = p.next statements is executed sequentially in the parent task, all dynamic instances of the remainder of the loop body can logically execute in parallel with each other.

Example 3 in Listing 1 shows the computation in Example 2 rewritten as a static void recursive method. You should first convince yourself that the computations in Examples 2 and 3 perform the same operations by omitting the async keyword in each case, and comparing the resulting sequential versions.

Example 4 shows the use of async to execute two method calls as parallel tasks (as was done in the two-way parallel sum algorithm).

As these examples show, a parallel program can create an unbounded number of tasks at runtime. The parallel runtime system is responsible for scheduling these tasks on a fixed number of processors. It does so by creating a fixed number of worker threads as shown in Figure 3, typically one worker per processor core. Worker threads are allocated by the Operating System (OS). By creating one thread per core, we limit the role of the OS in task scheduling to that of binding threads to cores at the start of program execution. The parallel runtime system takes over from that point onwards. These workers repeatedly pull work from
Logical Work Queue (async's & continuations)

Local variables are private to each task

Workers \( w_1 \) \( w_2 \) \( w_3 \) \( w_4 \)

pull work

push work

Static & instance fields are shared among tasks

Figure 3: Scheduling an parallel program on a fixed number of workers. (Figure adapted from [9].)

```
// Rule 1: a child async may read the value of any outer final local var
final int i1 = 1;
async { ... = i1; /* i1=1 */ }

// Rule 2: a child async may also read any "effectively final" outer local var
int i2 = 2; // i2=2 is copied on entry into the async like a method param
async { ... = i2; /* i2=2 */ }

// i2 cannot be modified again, if it is "effectively final"

// Rule 3: a child async is not permitted to modify an outer local var
int i3;
async { i3 = ...; /* ERROR */ }
```

Listing 2: Rules for accessing local variables across async's

A shared work queue when they are idle, and push work on the queue when they generate more work. The work queue entries can include async's and continuations. An async is the creation of a new task, such as \( T_1 \) in Figure 2. A continuation represents a potential suspension point for a task, which (as shown in in Figure 2) can include the point after an async creation as well as the point following the end of a finish scope. Continuations are also referred to as task-switching points, because they are program points at which a worker may switch execution between different tasks. A key motivation for this separation between tasks and threads is that it would be prohibitively expensive to create a new OS-level worker thread for each async task that is created in the program.

An important point to note in Figure 3 is that local variables are private to each task, whereas static and instance fields are shared among tasks. This is similar to the rule for accessing local variables and static/instance fields within and across methods or lambda expressions in Java. Listing 2 summarizes the rules for accessing local variables across async boundaries. For convenience, as shown in Rules 1 and 2, a child async is allowed to access a local variable declared in an outer async or method by simply capturing the value of the local variable when the async task is created (analogous to capturing the values of local variables in parameters at the start of a method call or in the body of a lambda expression). Note that a child async is not permitted to modify a local variable declared in an outer scope (Rule 3). If needed, you can work around the Rule 3 constraint by replacing the local variable by a static or instance field, since fields can be shared among tasks.

---

3This use of “continuation” is related to, but different from, continuations in functional programming languages.
1.1.2 Finish notation for Task Termination

The next parallel programming construct that we will learn as a complement to async is called finish. In pseudocode notation, “finish(stmt)” causes the parent task to execute ⟨stmt⟩, which includes the possible creation of async tasks, and then wait until all async tasks created within ⟨stmt⟩ have completed before the parent task can proceed to the statement following the finish. Async and finish statements may also be arbitrarily nested.

Thus, the finish statement in Figure 2 is used by task T0 to ensure that child task T1 has completed executing stmt1 before T0 executes stmt3. This may be necessary if stmt3 in Figure 2 used a value computed by stmt1. If T1 created a child async task, T2 (a “grandchild” of T0), T0 will wait for both T1 and T2 to complete in the finish scope before executing stmt3.

The waiting at the end of a finish statement is also referred to as a synchronization. The nested structure of finish ensures that no deadlock cycle can be created between two tasks such that each is waiting on the other due to end-finish operations. (A deadlock cycle refers to a situation where two tasks can be blocked indefinitely because each is waiting for the other to complete some operation.) We also observe that each dynamic instance TA of an async task has a unique dynamic Immediately Enclosing Finish (IEF) instance F of a finish statement during program execution, where F is the innermost finish containing TA. Like async, finish is a powerful primitive because it can be wrapped around any statement thereby supporting modularity in parallel programming.

If you want to convert a sequential program into a parallel program, one approach is to insert async statements at points where the parallelism is desired, and then insert finish statements to ensure that the parallel version produces the same result as the sequential version. Listing 3 extends the first two code examples from Listing 1 to show the sequential version, an incorrect parallel version with only async’s inserted, and a correct parallel version with both async’s and finish’s inserted.

The source of errors in the incorrect parallel versions are data races, which are notoriously hard to debug. As you will learn later in the course, a data race occurs if two parallel computations access the same shared location in an “interfering” manner i.e., such that at least one of the accesses is a write (so called because the effect of the accesses depends on the outcome of the “race” between them to determine which one completes first). Data races form a class of bugs that are specific to parallel programming.

async and finish statements also jointly define what statements can potentially be executed in parallel with each other. Consider the finish-async nesting structure shown in Figure 4. It reveals which pairs of statements can potentially execute in parallel with each other. For example, task A2 can potentially execute in parallel with tasks A3 and A4 since async A2 was launched before entering the finish F2, which is the Immediately Enclosing Finish for A3 and A4. However, Part 3 of Task A0 cannot execute in parallel with tasks A3 and A4 since it is performed after finish F2 is completed.

1.1.3 Array Sum with two-way parallelism

We can use async and finish to obtain a simple parallel program for computing an array sum as shown in Algorithm 2. The computation graph structure for Algorithm 2 is shown in Figure 5. Note that it differs from Figure 1 since there is no edge or sequence of edges connecting Tasks T2 and T3. This indicates that tasks T2 and T3 can execute in parallel with each other; for example, if your computer has two processor cores, T2 and T3 can be executed on two different processors at the same time. We will see much richer examples of parallel programs using async, finish and other constructs during the course.

1.2 Computation Graphs

A Computation Graph (CG) is a formal structure that captures the meaning of a parallel program’s execution. When you learned sequential programming, you were taught that a program’s execution could be understood as a sequence of operations that occur in a well-defined total order, such as the left-to-right evaluation order for expressions. Since operations in a parallel program do not occur in a fixed order, some other abstraction is needed to understand the execution of parallel programs. Computation Graphs address this need by focusing on the extensions required to model parallelism as a partial order. Specifically, a Computation
// Example 1: Sequential version
for (int i = 0; i < A.length; i++) A[i] = B[i] + C[i];
System.out.println(A[0]);

// Example 1: Incorrect parallel version
for (int ii = 0; ii < A.length; ii++) {
    final int i = ii; // i is a final variable
    async { A[i] = B[i] + C[i]; } // value of i is copied on entry to
} System.out.println(A[0]);

// Example 1: Correct parallel version
finish {
    for (int ii = 0; ii < A.length; ii++) {
        final int i = ii; // i is a final variable
        async { A[i] = B[i] + C[i]; } // value of i is copied on entry to
    }
} System.out.println(A[0]);

// Example 2: Sequential version
p = first;
while (p != null) {
    p.x = p.y + p.z; p = p.next;
} System.out.println(first.x);

// Example 2: Incorrect parallel version
pp = first;
while (pp != null) {
    T p = pp; // p is an effectively final variable
    async { p.x = p.y + p.z; } // value of p is copied on entry to async
    pp = pp.next;
} System.out.println(first.x);

// Example 2: Correct parallel version
pp = first;
finish while (pp != null) {
    T p = pp; // p is an effectively final variable
    async { p.x = p.y + p.z; } // value of p is copied on entry to async
    pp = pp.next;
} System.out.println(first.x);

Listing 3: Incorrect and correct parallelization with async and finish
Listing 4: Example usage of async and finish

```plaintext
finish { // F1
  // Part 1 of Task A0
  async { A1; async A2; }
  finish { // F2
    // Part 2 of Task A0
    async A3;
    async A4;
  }
  // Part 3 of Task A0
}
```

Figure 4: Finish-async nesting structure for code fragment in Listing 4

```
// Continuation of Task T1 (main program)
T1
T2
T3
// Continuation of Task T1
```

Figure 5: Computation graph for code example in Algorithm 2 (Two-way Parallel ArraySum)
Algorithm 2: Two-way Parallel ArraySum

Input: Array of numbers, $X$.
Output: $\text{sum} = \text{sum of elements in array } X$.

// Start of Task T1 (main program)
$\text{sum}_1 \leftarrow 0; \text{sum}_2 \leftarrow 0$;

// Compute $\text{sum}_1$ (lower half) and $\text{sum}_2$ (upper half) in parallel.
finish{
    async{
        // Task T2
        for $i \leftarrow 0$ to $X$.length/2 − 1 do
            $\text{sum}_1 \leftarrow \text{sum}_1 + X[i]$;
    };

    async{
        // Task T3
        for $i \leftarrow X$.length/2 to $X$.length − 1 do
            $\text{sum}_2 \leftarrow \text{sum}_2 + X[i]$;
    };
}

// Task T1 waits for Tasks T2 and T3 to complete
// Continuation of Task T1
$\text{sum} \leftarrow \text{sum}_1 + \text{sum}_2$;
return $\text{sum}$;

Graph consists of:

- A set of nodes, where each node represents a step consisting of an arbitrary sequential computation. For programs with async and finish constructs, a task’s execution can be divided into steps by using continuations to define the boundary points. Recall from Section 1.1.1 that a continuation point in a task is the point after an async creation or a point following the end of a finish scope. It is acceptable to introduce finer-grained steps in the CG if so desired, i.e., to split a step into smaller steps. The key constraint is that a step should not contain any parallelism or synchronization, i.e., a continuation point should not be internal to a step.

- A set of directed edges that represent ordering constraints among steps. For async−finish programs, it is useful to partition the edges into three cases [9]:

  1. **Continue** edges that capture sequencing of steps within a task — all steps within the same task are connected by a chain of continue edges.

  2. **Spawn** edges that connect parent tasks to child async tasks. When an async is created, a spawn edge is inserted between the step that ends with the async in the parent task and the step that starts the async body in the new child task.

  3. **Join** edges that connect descendant tasks to their Immediately Enclosing Finish (IEF) operations. When an async terminates, a join edge is inserted from the last step in the async to the step in the ancestor task that follows the IEF operation.

Consider the example program shown in Listing 5 and its Computation Graph shown in Figure 6. There are 6 tasks in the CG, $T_1$ to $T_6$. This example uses finer-grained steps than needed, since some steps (e.g., $v_1$ and $v_2$) could have been combined into a single step. In general, the CG grows as a program executes and a complete CG is only available when the entire program has terminated. The three classes of edges (continue, spawn, join) are shown in Figure 6. Even though they arise from different constructs, they all have the same effect viz., to enforce an ordering among the steps as dictated by the program.
In any execution of the CG on a parallel machine, a basic rule that must be obeyed is that a successor node \( B \) of an edge \((A, B)\) can only execute after its predecessor node \( A \) has completed. This relationship between nodes \( A \) and \( B \) is referred to as a **dependence** because the execution of node \( B \) depends on the execution of node \( A \) having completed. In general, node \( Y \) depends on node \( X \) if there is a path of directed edges from \( X \) to \( Y \) in the CG. Therefore, dependence is a **transitive** relation: if \( B \) depends on \( A \) and \( C \) depends on \( B \), then \( C \) must depend on \( A \). The CG can be used to determine if two nodes may execute in parallel with each other. For example, an examination of Figure 6 shows that all of nodes \( v_3 \ldots v_{15} \) can potentially execute in parallel with node \( v_{16} \) because there is no directed path in the CG from \( v_{16} \) to any node in \( v_3 \ldots v_{15} \) or vice versa.

It is also important to observe that the CG in Figure 6 is acyclic i.e., it is not possible to start at a node and trace a cycle by following directed edges that leads back to the same node. An important property of CGs is that all CGs are **directed acyclic graphs**, also referred to as **dags**. As a result, the terms “computation graph” and “computation dag” are often used interchangeably.

### 1.3 Ideal Parallelism

In addition to providing the dependence structure of a parallel program, Computation Graphs can also be used to reason about the ideal parallelism of a parallel program as follows:

- Assume that the execution time, \( \text{time}(N) \), is known for each node \( N \) in the CG. Since \( N \) represents an uninterrupted sequential computation, it is assumed that \( \text{time}(N) \) does not depend on how the CG is scheduled on a parallel machine. (This is an idealized assumption because the execution time of many operations, especially memory accesses, can depend on when and where the operations are performed in a real computer system.)

- Define \( \text{WORK}(G) \) to be the sum of the execution times of the nodes in CG \( G \),

\[
\text{WORK}(G) = \sum_{\text{node } N \text{ in } G} \text{time}(N)
\]

Thus, \( \text{WORK}(G) \) represents the total amount of work to be done in CG \( G \).

- Define \( \text{CPL}(G) \) to be the length of the longest path in \( G \), when adding up the execution times of all nodes in the path. There may be more than one path with this same length. All such paths are referred to as **critical paths**, so \( \text{CPL} \) stands for **critical path length**.

Consider again the CG, \( G \), in Figure 6. For simplicity, we assume that all nodes have the same execution time, \( \text{time}(N) = 1 \). It has a total of 23 nodes, so \( \text{WORK}(G) = 23 \). In addition the longest path consists of 17 nodes as follows, so \( \text{CPL}(G) = 17 \):

\[
v_1 \rightarrow v_2 \rightarrow v_3 \rightarrow v_6 \rightarrow v_7 \rightarrow v_8 \rightarrow v_{10} \rightarrow v_{11} \rightarrow v_{12} \rightarrow v_{13} \rightarrow v_{14} \rightarrow v_{18} \rightarrow v_{19} \rightarrow v_{20} \rightarrow v_{21} \rightarrow v_{22} \rightarrow v_{23}
\]

Given the above definitions of \( \text{WORK} \) and \( \text{CPL} \), we can define the **ideal parallelism** of Computation Graph \( G \) as the ratio, \( \text{WORK}(G)/\text{CPL}(G) \). The ideal parallelism can be viewed as the maximum performance improvement factor due to parallelism that can be obtained for computation graph \( G \), even if we ideally had an unbounded number of processors. It is important to note that ideal parallelism is independent of the number of processors that the program executes on, and only depends on the computation graph.

#### 1.3.1 Abstract Performance Metrics

While Computation Graphs provide a useful abstraction for reasoning about performance, it is not practical to build Computation Graphs by hand for large programs. The Habanero-Java (HJ) library used in the course includes the following utilities to help programmers reason about the CGs for their programs:

- **Insertion of calls to doWork()**. The programmer can insert a call of the form \( \text{perf.doWork}(N) \) anywhere in a step to indicate execution of \( N \) application-specific abstract operations e.g., floating-point
Listing 5: Example program

```plaintext
1 // Task T1
2 v1; v2;
3 finish {
4    async {
5        // Task T2
6        v3;
7        finish {
8            async { v4; v5; } // Task T3
9            v6;
10           async { v7; v8; } // Task T4
11            v9;
12        } // finish
13        v10; v11;
14           async { v12; v13; v14; } // Task T5
15            v15;
16        } // finish
17        v16; v17;
18    } // finish
19        v18; v19;
20    finish {
21        async { v20; v21; v22; }
22    }
23   v23;
```

Figure 6: Computation Graph $G$ for example program in Listing 5
operations, comparison operations, stencil operations, or any other data structure operations. Multiple calls to `perf.doWork()` are permitted within the same step. They have the effect of adding to the abstract execution time of that step. The main advantage of using abstract execution times is that the performance metrics will be the same regardless of which physical machine the HJ program is executed on. The main disadvantage is that the abstraction may not be representative of actual performance on a given machine.

- **Printout of abstract metrics.** If an HJlib program is executed with a specified option, abstract metrics are printed at the end of program execution that capture the total number of operations executed (`WORK`) and the critical path length (`CPL`) of the CG generated by the program execution. The ratio, `WORK/CPL` is also printed as a measure of ideal parallelism.

- **Visualization of computation graph.** A tool called HJ-viz is also provided that enables you to see an image of the computation graph of a program executed with abstract performance metrics.

### 1.4 Multiprocessor Scheduling

Now, let us discuss the execution of CG $G$ on an idealized parallel machine with $P$ processors. It is idealized because all processors are assumed to be identical, and the execution time of a node is assumed to be independent of which processor it executes on. Consider all legal schedules of $G$ on $P$ processors. A legal schedule is one that obeys the dependence constraints in the CG, such that for every edge $(A, B)$ the scheduled guarantees that $B$ is only scheduled after $A$ completes. Let $t_P$ denote the execution time of a legal schedule. While different schedules may have different execution times, they must all satisfy the following two lower bounds:

1. **Capacity bound:** $t_p \geq \frac{WORK(G)}{P}$. It is not possible for a schedule to complete in time less than $\frac{WORK(G)}{P}$ because that’s how long it would take if all the work was perfectly divided among $P$ processors.

2. **Critical path bound:** $t_p \geq CPL(G)$. It is not possible for a schedule to complete in time less than $CPL(G)$ because any legal schedule must obey the chain of dependences that form a critical path. Note that the critical path bound does not depend on $P$.

Putting these two lower bounds together, we can conclude that $t_p \geq \max\left(\frac{WORK(G)}{P}, CPL(G)\right)$. Thus, if the observed parallel execution time $t_P$ is larger than expected, you can investigate the problem by determining if the capacity bound or the critical path bound is limiting its performance.

It is also useful to reason about the upper bounds for $t_P$. To do so, we have to make some assumption about the “reasonableness” of the scheduler. For example, an unreasonable scheduler may choose to keep processors idle for an unbounded number of time slots (perhaps motivated by locality considerations), thereby making $t_P$ arbitrarily large. The assumption made in the following analysis is that all schedulers under consideration are “greedy” i.e., they will never keep a processor idle when there’s a node that is available for execution.

We can now state the following properties for $t_P$, when obtained by greedy schedulers:

- $t_1 = WORK(G)$. Any greedy scheduler executing on 1 processor will simply execute all nodes in the CG in some order, thereby ensuring that the 1-processor execution time equals the total work in the CG.

- $t_\infty = CPL(G)$. Any greedy scheduler executing with an unbounded (infinite) number of processors must complete its execution with time = $CPL(G)$, since all nodes can be scheduled as early as possible.

- $t_P \leq t_1/P + t_\infty = \frac{WORK(G)}{P} + CPL(G)$. This is a classic result due to Graham [8]. An informal sketch of the proof is as follows. At any given time in the schedule, we can declare the time slot to be complete if all $P$ processors are busy at that time and incomplete otherwise. The number of complete time slots must add up to at most $t_1/P$ since each such time slot performs $P$ units of work.
In addition, the number of incomplete time slots must add up to at most $t_{\infty}$ since each such time slot must advance 1 time unit on a critical path. Putting them together results in the upper bound shown above. Combining it with the lower bound, you can see that:

$$\max(\frac{\text{WORK}(G)}{P}, \text{CPL}(G)) \leq t_{P} \leq \frac{\text{WORK}(G)}{P} + \text{CPL}(G)$$

It is interesting to compare the lower and upper bounds above. You can observe that they contain the $\max$ and $\sum$ of the same two terms, $\text{WORK}(G)/P$ and $\text{CPL}(G)$. Since $x + y \leq 2 \max(x, y)$, the lower and upper bounds vary by at most a factor of $2\times$. Further, if one term dominates the other e.g., $x \gg y$, then the two bounds will be very close to each other.

### 1.5 Parallel Speedup and Amdahl’s Law

Given definitions for $t_{1}$ and $t_{P}$, the speedup for a given schedule of a computation graph on $P$ processors is defined as $\text{Speedup}(P) = \frac{t_{1}}{t_{P}}$. $\text{Speedup}(P)$ is the factor by which the use of $P$ processors speeds up execution time relative to 1 processor, for a fixed input size. For ideal executions without overhead, $1 \leq \text{Speedup}(P) \leq P$. The term linear speedup is used for a program when $\text{Speedup}(P) = k \times P$ as $P$ varies, for some constant $k$, $0 < k < 1$.

We can now summarize a simple observation made by Gene Amdahl in 1967 [1]: if $q \leq 1$ is the fraction of $\text{WORK}$ in a parallel program that must be executed sequentially, then the best speedup that can be obtained for that program, even with an unbounded number of processors, is $\text{Speedup}(P) \leq 1/q$. As in the Computation Graph model studied earlier, this observation assumes that all processors are uniform i.e., they all execute at the same speed.

This observation follows directly from a lower bound on parallel execution time that you are familiar with, namely $t_{P} \geq \text{CPL}(G)$, where $t_{P}$ is the execution time of computation graph $G$ on $P$ processors and $\text{CPL}$ is the critical path length of graph $G$. If fraction $q$ of $\text{WORK}(G)$ is sequential, it must be the case that $\text{CPL}(G) \geq q \times \text{WORK}(G)$. Therefore, $\text{Speedup}(P) = \frac{t_{1}}{t_{P}}$ must be $\leq \frac{\text{WORK}(G)}{(q \times \text{WORK}(G))} = 1/q$ since $t_{1} = \text{WORK}(G)$ for greedy schedulers.
The consequence of Amdahl’s Law is illustrated in Figure 7. The x-axis shows the number of processors increasing in powers of 2 on a log scale, and the y-axis represents speedup obtained for different values of $q$. Specifically, each curve represents a different value for the parallel portion, $(1 - q)$, assuming that all the non-sequential work can be perfectly parallelized. Even when the parallel portion is as high as 95%, the maximum speedup we can obtain is $20 \times$ since the sequential portion is 5%. The ideal case of $q = 0$ and a parallel portion of 100% is not shown in the figure, but would correspond to the $y = x$ line which would appear to be an exponential curve since the x-axis is plotted on a log scale.

Amdahl’s Law reminds us to watch out for sequential bottlenecks both when designing parallel algorithms and when implementing programs on real machines. While it may paint a bleak picture of the utility of adding more processors to a parallel computing, it has also been observed that increasing the data size for a parallel program can reduce the sequential portion [11] thereby making it profitable to utilize more processors. The ability to increase speedup by increasing the number of processors for a fixed input size (fixed WORK) is referred to as strong scaling, and the ability to increase speedup by increasing the input size (increasing WORK) is referred to as weak scaling.
2 Functional Parallelism and Determinism

2.1 Future Tasks and Functional Parallelism

2.1.1 Tasks with Return Values

The `async` construct introduced in previous sections provided the ability to execute any statement as a parallel task, and the `finish` construct provided a mechanism to await termination of all tasks created within its scope. `async` task creation leads to a natural `parent-child` relation among tasks, e.g., if task $T_A$ creates async task $T_B$, then $T_A$ is the parent of $T_B$ and $T_B$ is the child of $T_A$. Thus, an `ancestor` task, $T_A$, can use a `finish` statement to ensure that it is safe to read values computed by all descendant tasks $T_D$ enclosed in the scope of the `finish`. These values are communicated from $T_D$ to $T_A$ via shared variables, which (in the case of Java tasks) must be an instance field, static field, or array element.

However, there are many cases where it is desirable for a task to explicitly wait for the return value from a specific single task, rather than all descendant tasks in a `finish` scope. To do so, it is necessary to extend the regular `async` construct with return values, and to create a container (proxy) for the return value which is done using `future objects` as follows:

- A variable of type `future<T>` is a reference to a `future` object i.e., a container for a return value of type $T$ from an `async` task.

- There are exactly two operations that can be performed on a variable, $V_1$, of type `future<T1>`, assuming that type $T_2$ is a subtype of, or the same as, type $T_1$:
  
  1. Assignment — variable $V_1$ can be assigned a reference to an `async` with return value type $T_2$ as described below, or $V_1$ can be assigned the value of a variable $V_2$ with type `future<T2>`.
  2. Blocking read — the operation, $V_1.get()$, waits until the `async` referred to by $V_1$ has completed, and then propagates the return value of the `async` to the caller as a value of type $T_1$. This semantics also avoids the possibility of a race condition on the return value.

- An `async` with a return value is called a `future task`, and can be defined by introducing two extensions to regular `async`'s as follows:
  
  1. The body of the `async` must start with a type declaration, `async<T1>`, in which the type of the `async`'s return value, $T_1$, immediately follows the `async` keyword.
  2. The body itself must consist of a compound statement enclosed in `{ }` braces, dynamically terminating with a `return` statement. It is important to note that the purpose of this `return` statement is to communicate the return value of the enclosing `async` and not the enclosing method.

Listing 6 revisits the two-way parallel array sum example discussed earlier, but using `future tasks` instead of regular `async`'s. There are two variables of type `future<int>` in this example, `sum1` and `sum2`. Each future task can potentially execute in parallel with its parent, just like regular `async`'s. However, unlike regular `async`'s, there is no `finish` construct needed for this example since the parent task $T_1$, performs `sum1.get()` to wait for future task $T_2$ and `sum2.get()` to wait for future task $T_3$.

In addition to waiting for completion, the `get()` operations are also used to access the return values of the future tasks. This is an elegant capability because it obviates the need for shared fields or shared arrays, and avoids the possibility of race conditions on those shared variables. Notice the three declarations for variables `sum` in lines 4, 9, and 14. Each occurrence of `sum` is local to a task, and there’s no possibility of race conditions on these local variables or the return values from the future tasks. These properties have historically made future tasks well suited to express parallelism in functional languages [12].

---

4“future” is a pseudocode keyword, and will need be replaced by the appropriate data type in real code.
Future tasks can be accommodated very naturally in the Computation Graph (CG) abstraction introduced in Section 1.2. The main CG extensions required to accommodate the `get()` operations are as follows:

- A `get()` operation is a new kind of continuation operation, since it can involve a blocking operation. Thus, `get()` operations can only occur on the boundaries of steps. To fully realize this constraint, it may be necessary to split a statement containing one or more `get()` operations into multiple sub-statements such that a `get()` occurs in a sub-statement by itself.

- A `spawn` edge connects the parent task to a child future task, just as with regular `async`'s.

- When a future task, $T_F$, terminates, a `join` edge is inserted from the last step in $T_F$ to the step in the ancestor task that follows its Immediately Enclosing Finish (IEF) operation, as with regular `async`'s. In addition, a `join` edge is also inserted from $T_F$'s last step to every step that follows a `get()` operation on the future task. Note that new `get()` operations may be encountered even after $T_F$ has terminated.

To compute the computation graph for the example in Listing 6, we will need to split the statement in line 14 into the following sub-statements:

14a int temp1 = sum1.get();
14b int temp2 = sum2.get();
14c int sum = temp1 + temp2;

The resulting CG is shown in Figure 8. Note that the end of each step in a future task has two outgoing `join` edges in this example, one to the `get()` operation and one to the implicit end-finish operation in the main program.

2.1.3 Why should future references be effectively final?

In this section, we elaborate on an important programming principle for futures, viz., all variables containing references to future objects should be effectively final (either declared final or participating in a single assignment), which means that the variable cannot be modified after initialization. To motivate this rule, consider the buggy program example in Listing 7.

```java
Listing 7: Buggy Parallel ArraySum using Future Tasks
```

This program declares two static non-final future reference fields, `f1` and `f2`, in lines 1 and 2 and initializes them to `null`. The `main()` programs then creates two future tasks, $T1$ and $T2$, in lines 5 and 6 and assigns
them to $f_1$ and $f_2$ respectively. Task $T_1$ uses a “spin loop” in line 10 to wait for $f_2$ to become non-null, and task $T_2$ does the same in line 15 to wait for $f_1$ to become non-null. After exiting the spin loop, each task performs a `get()` operation on the other thereby attempting to create a deadlock cycle in the computation graph. Fortunately, the rule that all variables containing references to future objects should be effectively final can avoid this situation.

### 2.1.4 Future Tasks with a void return type

A key distinction made thus far between future tasks and regular async’s is that future tasks have return values but regular async’s do not. However, there is a construct that represents a hybrid of these two task variants, namely a future task, $T_V$, with a void return type. This is analogous to Java methods with void return types. In this case, a `get()` operation performed on $T_V$ has the effect of waiting for $T_V$ to complete, but no return value is communicated from $T_V$.

Figure 9 shows Computation Graph $G_3$ that cannot be generated using only async and finish constructs, and Listing 8 shows the code that can be used to generate $G_3$ using future tasks. This code uses futures with a void return type, and provides a systematic way of converting any CG into a task-parallel program using futures.

### 2.2 Memoization

The basic idea of memoization is to remember results of function calls $f(x)$ as follows:

1. Create a data structure that stores the set $\{(x_1,y_1 = f(x_1)),(x_2,y_2 = f(x_2)),\ldots\}$ for each call $f(x_i)$ that returns $y_i$.

2. Look up data structure when processing calls of the form $f(x')$ when $x'$ equals one of the $x_i$ inputs for which $f(x_i)$ has already been computed.

The memoization pattern lends itself easily to parallelization using futures by modifying the memoized data structure to store $\{(x_1,y_1 = \text{future}(f(x_1))), (x_2,y_2 = \text{future}(f(x_2))),\ldots\}$. The lookup operation can then be extended with a `get()` operation on the future value if a future has already been created for the result of a given input.
static future<int> f1=null;
static future<int> f2=null;

static void main(String[] args) {
    f1 = async<int>{return a1();}; // Task T1
    f2 = async<int>{return a2();}; // Task T2
}

int a1() {
    while (f2 == null); // spin loop
    return f2.get(); // T1 waits for T2
}

int a2() {
    while (f1 == null); // spin loop
    return f1.get(); // T2 waits for T1
}

// Predefined reduction
accum(Operator op, Class dataType); // Constructor
void accum.put(Number datum); // Remit a datum
void accum.put(int datum);
void accum.put(double datum);
Number accum.get(); // Retrieve the result

// User-defined reduction
interface reducible<T> {
    void reduce(T arg); // Define reduction
    T identity(); // Define identity
}
accum<T>(Operator op, Class dataType); // Constructor
void accum.put(T datum); // Remit a datum
T accum.customGet(); // Retrieve the result

Figure 10: Example of accumulator API

2.3 Finish Accumulators

In this section, we introduce the programming interface and semantics of finish accumulators. Finish accumulators support parallel reductions, which represent a common pattern for computing the aggregation of an associative and commutative operation, such as summation, across multiple pieces of data supplied by parallel tasks. There are two logical operations, put, to remit a datum and get, to retrieve the result from a well-defined synchronization (end-finish) point. Section 2.3.1 describes the details of these operations, and Section 2.3.2 describes how user-defined reductions are supported in finish accumulators.

2.3.1 Accumulator Constructs

Figure 10 shows an example of a finish-accumulator programming interface. The operations that a task, $T_i$, can perform on accumulator, $ac$, are defined as follows.

- **new**: When task $T_i$ performs a “$ac = new$ accumulator(op, dataType);” statement, it creates a new accumulator, $ac$, on which $T_i$ is registered as the owner task. Here, $op$ is the reduction operator that the accumulator will perform, and $dataType$ is the type of the data upon which the accumulator operates. Currently supported predefined reduction operators include SUM, PROD, MIN, and MAX; CUSTOM is used to specify user-defined reductions.

- **put**: When task $T_i$ performs an “$ac.put(datum);$” operation on accumulator $ac$, it sends datum to ac for the accumulation, and the accumulated value becomes available at a later end-finish point. The runtime system throws an exception if a put() operation is attempted by a task that is not the owner and does not belong to a finish scope that is associated with the accumulator. When a task performs multiple put() operations on the same accumulator, they are treated as separate contributions to the reduction.

- **get**: When task $T_i$ performs an “$ac.get();$” operation on accumulator $ac$ with predefined reduction operators, it obtains a Number object containing the accumulated result. Likewise “$ac.customGet();$” on $ac$ with a CUSTOM operator returns a user-defined $T$ object with the accumulated result. When no put is performed on the accumulator, get returns the identity element for the operator, e.g., 0 for SUM, 1 for PROD, MAX_VALUE/MIN_VALUE for MIN/MAX, and user-defined identity for CUSTOM.

- **Summary of access rules**: The owner task of accumulator $ac$ is allowed to perform put/get operations on $ac$ and associate $ac$ with any finish scope in the task. Non-owner tasks are allowed to
access `ac` only within `finish` scopes with which `ac` is associated. To ensure determinism, the accumulated result only becomes visible at the end-finish synchronization point of an associated `finish`; `get` operations within a `finish` scope return the same value as the result at the beginning of the `finish` scope. Note that `put` operations performed by the owner outside associated `finish` scopes are immediately reflected in any subsequent `get` operations since those results are deterministic.

In contrast to traditional reduction implementations, the `put()` and `get()` operations are separate, and reduction results are not visible until the end-finish point.

To associate a `finish` statement with multiple accumulators, $T_{owner}$ can perform a special `finish` statement of the form, “`finish (ac_1, ac_2, \ldots, ac_n)(stmt)`”. Note that `finish (ac)` becomes a no-op if `ac` is already associated with an outer `finish` scope.

Figure 11 shows an example where four tasks $T_0$, $T_1$, $T_2$, and $T_3$ access a finish accumulator `ac`. As described earlier, the `put` operation by $T_1$ throws an exception due to nondeterminism since it is not the owner and was created outside the `finish` scope associated with accumulator `ac`. Note that the inner `finish` scope has no impact on the reduction of `ac` since `ac` is associated only with the outer `finish`. All `put` operations by $T_0$, $T_2$, and $T_3$ are reflected in `ac` at the end-finish synchronization of the outer `finish`, and the result is obtained by $T_0$’s `get` operation.

2.3.2 User-defined Reductions

User-defined reductions are also supported in finish accumulators, and its usage consists of these three steps:
1) specify `CUSTOM` and `reducible.class` as the accumulator’s operator and type,
2) define a class that implements the `reducible` interface,
3) pass the implementing class to the accumulator as a type parameter.

Figure 12 shows an example of a user-defined reduction. Class `Coord` contains two double fields, $x$ and $y$, and the goal of the reduction is to find the furthest point from the origin among all the points submitted to the accumulator. The `reduce` method computes the distance of a given point from the origin, and updates $x$ and $y$ if `arg` has a further distance than the current point in the accumulator.

2.4 Map Reduce

Data structures based on key-value pairs are used by a wide range of data analysis algorithms, including web search and statistical analyses. In Java, these data structures are often implemented as instances of the `Map` interface. An important constraint imposed on sets of key-value pairs is that no key occurs more than once, thereby ensuring that each key can map to at most one value. Thus, a mathematical abstraction of a
1: void foo() {
2:   accum<Coord> ac = new accum<Coord>(Operation.CUSTOM,
3:                                             reducible.class);
4:   finish(ac) {
5:     forasync (point [j] : [1:n]) {
6:       while(check(j)) {
7:         ac.put(getCoordinate(j));
8:     } }
9:   Coord c = ac.customGet();
10:  System.out.println("Furthest: " + c.x + ", " + c.y);
11: }
12: }
13: class Coord implements reducible<Coord> {
14:   public double x, y;
15:   public Coord(double x0, double y0) {
16:     x = x0; y = y0;
17:   }
18:   public Coord identity(); {
19:     return new Coord(0.0, 0.0);
20:   }
21:   public void reduce(Coord arg) {
22:     if (sq(x) + sq(y) < sq(arg.x) + sq(arg.y)) {
23:       x = arg.x; y = arg.y;
24:     }
25:   }
26:   private double sq(double v) { return v * v; }
27: }

Figure 12: User-defined reduction example

Map data structure is as a set of pairs, \( S = \{(k_1, v_1), \ldots, (k_n, v_n)\} \), such that each \((k_i, v_i)\) pair consists of a key, \( k_i \), and a value, \( v_i \), and \( k_i \neq k_j \) for any \( i \neq j \).

Many data analysis algorithms can be specified as sequences of \textit{map} and \textit{reduce} operations on sets of key-value pairs. For a given key-value pair, \((k_i, v_i)\), a map function \( f \) generates a set of output key-value pairs, \( f(k_i, v_i) = \{(k_1, v_1), \ldots, (k_m, v_m)\} \). The \( k_j \) keys can be different from the \( k_i \) key in the input of the map function. When applied to a set of key-value pairs, the map function results in the union of the output set generated from each input key-value pair as follows:

\[
 f(S) = \bigcup_{(k_i, v_i) \in S} f(k_i, v_i)
\]

\( f(S) \) is referred to as a set of \textit{intermediate key-value pairs} because it will serve as an input for a reduce operation, \( g \). Note that it is possible for \( f(S) \) to contain multiple key-value pairs with the same key. The reduce operation groups together intermediate key-value pairs, \( \{(k, v_j)\} \) with the same key \( k \), and generates a reduced key-value pair, \((k, v)\), for each such \( k \), using a reduce function \( g \) on all \( v_j \) values with the same intermediate key \( k' \). Therefore \( g(f(S)) \) is guaranteed to satisfy the unique-key property.

Listing 9 shows the pseudocode for one possible implementation of map-reduce operations using finish and async primitives. The basic idea is to complete all operations in the map phase before any operation in the reduce phase starts. Alternate implementations are possible that expose more parallelism.

As an example, Listing 10 shows how the \textit{WordCount} problem can be solved using map and reduce operations on sets of key-value pairs. All map operations in step a) (line 4) can execute in parallel with only local data accesses, making the map step highly amenable to parallelization. Step b) (line 5) can involve a major reshuffle of data as all key-value pairs with the same key are grouped (gathered) together. Finally, step c) (line 6) performs a standard reduction algorithm for all values with the same key.
1. **Input**: set of words
2. **Output**: set of (word, count) pairs
3. **Algorithm**:
   a) For each input word W, emit (W, 1) as a key-value pair (map step).
   b) Group together all key-value pairs with the same key (intermediate key-value pairs).
   c) Perform a sum reduction on all values with the same key (reduce step).

Listing 10: Computing Wordcount using map and reduce operations on sets of key-value pairs
2.5 Data Races

2.5.1 What are Data Races?

The fundamental primitives for task creation (async) and termination (finish) that you have learned thus far are very powerful, and can be used to create a wide range of parallel programs. You will now learn about a pernicious source of errors in parallel programs called data races, and how to avoid them.

Consider the example program shown in Listing 11. The parallel version contains an error because the writes to instances of `p.x` in line 7 can potentially execute in parallel with the reads of instances of `p.x` in line 9. This can be confirmed by building a computation graph for the program and observing that there is no chain of dependence edges from step instances of line 7 to step instances of line 9. As a result, it is unclear whether a read in line 9 will receive an older value of `p.x` or the value written in line 7. This kind of situation, where the outcome depends on the relative completion times of two events, is called a race condition. When the race condition applies to read and write accesses on a shared location, it is called a data race. A shared location must be a static field, instance field or array element, since it is not possible for interfering accesses to occur in parallel on a local variable in a method.

Data races are a challenging source of errors in parallel programming, since it is usually impossible to guarantee that all possible orderings of the accesses to a location will be encountered during program testing. Regardless of how many tests you write, so long as there is one ordering that yields the correct answer it is always possible that the correct ordering in encountered when testing your program and an incorrect ordering is encountered when the program executes in a production setting. For example, while testing the program, it is possible that the task scheduler executes all the async tasks in line 7 of Listing 11 before executing the continuation starting at line 8. In this case, the program will appear to be correct during test, but will have a latent error that could be manifest at any arbitrary time in the future.

Formally, a data race occurs on location \( L \) in a program execution with computation graph \( CG \) if there exist steps \( S_1 \) and \( S_2 \) in \( CG \) such that:

1. \( S_1 \) does not depend on \( S_2 \) and \( S_2 \) does not depend on \( S_1 \) i.e., there is no path of dependence edges from \( S_1 \) to \( S_2 \) or from \( S_2 \) to \( S_1 \) in \( CG \), and

2. both \( S_1 \) and \( S_2 \) read or write \( L \), and at least one of the accesses is a write.

Programs that are guaranteed to never exhibit a data race are said to to be data-race-free. It is also common to refer to programs that may exhibit data races as “racy”.

There are a number of interesting observations that follow from the above definition of a data race:

1. **Immutability property: there cannot be a data race on shared immutable data.** Recall that shared data in a parallel Habanero-Java program consists of static fields, instance fields, and array elements. An immutable location, \( L_i \), is one that is only written during initialization, and can only be read after

```
// Sequential version
for ( p = first ; p != null ; p = p.next ) p.x = p.y + p.z;
for ( p = first ; p != null ; p = p.next ) sum += p.x;

// Incorrect parallel version
for ( p = first ; p != null ; p = p.next )
    async p.x = p.y + p.z;
for ( p = first ; p != null ; p = p.next )
    sum += p.x;
```

Listing 11: Sequential and incorrect parallel versions of example program
initialization. In this case, there cannot be a data race on \( L_i \) because there will only be one step that writes to \( L_i \) in CG, and all steps that read from \( L \) must follow the write. This property applies by definition to static and non-static final fields. It also applies to instances of any immutable class e.g., java.lang.String.

2. Single-task ownership property: there cannot be a data race on a location that is only read or written by a single task. Let us say that step \( S_i \) in CG owns location \( L \) if it performs a read or write access on \( L \). If step \( S_i \) belongs to Task \( T_j \), we can also say that Task \( T_j \) owns \( L \) when executing \( S_i \). (Later in the course, it will be useful to distinguish between read ownership and write ownership.) Consider a location \( L \) that is only owned by steps that belong to the same task, \( T_j \). Since all steps in Task \( T_j \) must be connected by continue edges in CG, all reads and writes to \( L \) must be ordered by the dependences in CG. Therefore, no data race is possible on location \( L \).

3. Ownership-transfer property: there cannot be a data race on a location if all steps that read or write it are totally ordered in CG. The single-task-ownership property can be generalized to the case when all steps that read or write a location \( L \) are totally ordered by dependences in CG, even if the steps belong to different tasks i.e., for any two steps \( S_i \) and \( S_j \) that read or write \( L \), it must be the case that there is a path of dependence edges from \( S_i \) to \( S_j \) or from \( S_j \) to \( S_i \). In this case, no data race is possible on location \( L \). We can think of the ownership of \( L \) being “transferred” from one step to another, even across task boundaries, as execution follows the path of dependence edges.

4. Local-variable ownership property: there cannot be a data race on a local variable. If \( L \) is a local variable, it can only be written by the task in which it is declared (\( L \)'s owner). Though it may be read by a descendant task, the “copy-in” semantics for local variables (Rule 2 in Listing 2 of Section 1.1.1) ensures that the value of the local variable is copied on async creation thus ensuring that there is no race condition between the read access in the descendant task and the write access in \( L \)'s owner.

2.5.2 Avoiding Data Races

The four observations in Section 2.5.1 directly lead to the identification of programming tips and best practices to avoid data races. There is considerable effort under way right now in the research community to provide programming language support for these best practices, but until they enter the mainstream it is your responsibility as a programmer to follow these tips on avoiding data races:

1. Immutability tip: Use immutable objects and arrays as far as possible. Sometimes this may require making copies of objects and arrays instead of just modifying a single field or array element. Depending on the algorithm used, the overhead of copying could be acceptable or prohibitive. For example, copying has a small constant factor impact in the Parallel Quicksort algorithm.

Consider the example program in Listing 12. The parent task initializes \( s1 \) to the string, ”XYZ” in line 2, creates a child task in line 3, and prints out \( s1 \) in line 4. Even though the child task invokes the toLowerCase() method on \( s1 \) in line 3, there is no data race between line 3 and the parent task’s print statement in line 4 because toLowerCase() returns a new copy of the string with the lower-case conversion instead of attempting to update the original version.
2. **Single-task ownership tip:** If an object or array needs to be written multiple times after initialization, then try and restrict its ownership to a single task. This will entail making copies when sharing the object or array with other tasks. As in the Immutability tip, it depends on the algorithm whether the copying overhead can be acceptable or prohibitive.

In the example in Listing 13, the parent Task T1 allocates and initializes array A in lines 2 and 3, and creates an async child Task T2 to compute its sum in line 6. Task T2 calls the `computeSum()` method that actually modifies its input array. To avoid a data race, Task T1 acts as the owner of array A and creates a copy of A in array B in lines 4 and 5. Task T2 becomes the owner of B, while Task T1 remains the owner of A thereby ensuring that each array is owned by a single task.

3. **Ownership-transfer tip:** If an object or array needs to be written multiple times after initialization and also accessed by multiple tasks, then try and ensure that all the steps that read or write a location L in the object/array are totally ordered by dependences in CG. Ownership transfer is even necessary to support single-task ownership. In Listing 13, since Task T1 initializes array B as a copy of array A, T1 is the original owner of A. The ownership of B is then transferred from T1 to T2 when Task T2 is created with the async statement.

4. **Local-variable tip:** You do not need to worry about data races on local variables, since they are not possible. However, local variables in Java are restricted to contain primitive data types (such as int) and references to objects and arrays. In the case of object/array references, be aware that there may be a data race on the underlying object even if there is no data race on the local variable that refers to (points to) the object.

You will learn additional mechanisms for avoiding data races later in the course, when you study the future, phaser, accumulator, isolated and actor constructs.

2.6 **Functional and Structural Determinism**

A computation is said to be *functionally deterministic* if it always computes the same answer, when given the same inputs. By default, any sequential computation is expected to be deterministic with respect to its inputs; if the computation interacts with the environment (e.g., a GUI event such as a mouse click, or a system call like `System.nanoTime()`) then the values returned by the environment are also considered to be inputs to the computation. Further, a computation is said to be *structurally deterministic* if it always computes the same computation graph, when given the same inputs.

The presence of data races often leads to functional and/or structural nondeterminism because a parallel program with data races may exhibit different behaviors for the same input, depending on the relative scheduling and timing of memory accesses involved in a data race. In general, the absence of data races...
is not sufficient to guarantee determinism. However, the parallel constructs introduced in this module (“Module 1: Determinism”) were carefully selected to ensure the following Determinism Property:

If a parallel program is written using the constructs introduced in Module 1 and is guaranteed to never exhibit a data race, then it must be both functionally and structurally deterministic.

Note that the determinism property states that all data-race-free programs written using the constructs introduced in Module 1 are guaranteed to be deterministic, but it does not imply that all racy programs are non-deterministic.

The determinism property is a powerful semantic guarantee since the constructs introduced in Module 1 span a wide range of parallel programming primitives that include `async`, `finish`, `finish accumulators`, `futures`, `data-driven tasks (async await)`, `forall`, `barriers`, `phasers`, and `phaser accumulators`. The notable exceptions are critical sections, isolated statements, and actors, all of which will be covered in Module 2 (“Concurrency”).

### 2.6.1 Optional topic: Memory Models and assumptions that can be made in the presence of Data Races

Since the current state-of-the-art lacks a fool-proof approach for avoiding data races, this section briefly summarizes what assumptions can be made for parallel programs that may contain data races.

A memory consistency model, or memory model, is the part of a programming language specification that defines what write values a read may see in the presence of data races. Consider the example program in Listing 14. It exhibits multiple data races since location `p.x` can potentially be written in parallel by Tasks `T1` and `T2` and read in parallel by Tasks `T3` and `T4`. `T3` and `T4` each read and print the value of `p.x` three times. (Note that `q.x` and `p.x` both refer to the same location.) It is the job of the memory model to specify what outputs are legally permitted by the programming language.

There is a wide spectrum of memory models that have been proposed in the literature. We briefly summarize three models for now, and defer discussion of a fourth model, the Java Memory Model, to later in the course:

1. Sequential Consistency: The Sequential Consistency (SC) memory model was introduced by Leslie Lamport in 1979 [13] and builds on a simple but strong rule viz., all steps should observe writes to all locations in the same order. Thus, the SC memory model will not permit Task `T3` to print “0, 1, 2” and Task `T4` to print “0, 2, 1”.

While the SC model may be intuitive for expert system programmers who write operating systems and multithreaded libraries such as `java.util.concurrent`, it can lead to non-obvious consequences for
async {  // Task T3
    int p.x = p.x;
    System.out.println("First read = " + p.x);
    System.out.println("Second read = " + q.x);
    System.out.println("Third read = " + p.x);
}

Listing 15: Rewrite of Task T3 from Listing[14]

mainstream application programmers. For example, suppose an application programmer decided to rewrite the body of Task T3 as shown in Listing[15]. The main change is to introduce a local variable p.x that captures the value of p.x in line 2, and replaces p.x by p.x in lines 3 and 5. This rewrite is perfectly legal for a sequential program, and should be legal for computations performed within a sequential step. However, a consequence of this rewrite is that Task T3 may print “0, 1, 0” as output, which would not be permitted by the SC model. Thus, an apparently legal code transformation within a sequential step has changed the semantics of the parallel program under the SC model.

2. Location Consistency: The Location Consistency (LC) memory model[7] was introduced to provide an alternate semantics to address the code transformation anomalies that follow from the SC model. The LC rule states that a read of location L in step S_i may receive the value from any Most Recent Write (MRW) of L relative to S_i in the CG. A MRW is a write operation that can potentially execute in parallel with S_i, or one that precedes S_i by a chain of dependence edges such that there is no other write of L on that chain. LC is a weaker model than SC because it permits all the outputs that SC does, as well as additional outputs that are not permitted by SC. For the program in Listing[14], the LC model permits Task T3 to print “0, 1, 2” and Task T4 to print “0, 2, 1” in the same execution, and also permits Task T3 to print “0, 1, 0” in a different execution.

3. C++ Memory Model: The proposed memory model for the new C++0x standard[4] makes the following assumption about data races:

“We give no semantics to programs with data races. There are no benign C++ data races.”

A data race that cannot change a program’s output with respect to its inputs is said to be benign. A special case of benign races is when all write accesses to a location L (including the initializing write) write the same value to L. It is benign, because it does not matter how many writes have been performed on L before a read occurs, since all writes update L with the same value.

Thus, the behavior of a program with data races is completely undefined in the C++ memory model. While this approach may be acceptable for systems programming languages like C/C++, it is unacceptable for type-safe languages like Java that rely on basic safety guarantees for pointers and memory accesses.

Why should you care about these memory models if you write bug-free code without data races? Because the code that you write may be used in conjunction with other code that causes your code to participate in a data race. For example, if your job to provide a sequential method that implements the body of Task T3 in Listing[14] the program that uses your code may exhibit data races even though your code may be free of bugs. In that case, you should be aware what the impact of data races may be on the code that you have written, and whether or not a transformation such as the one in Listing[15] is legal. The type of the shared location also impacts the assumptions that you make. On some systems, the guarantees for 64-bit data types such as long and double are weaker than those for smaller data types such as int and Java object references.
3 Loop-level Parallelism

3.1 Parallel Loops

As mentioned earlier, the `finish` and `async` constructs can be used to create parallel loops using the `finish–for–async` pattern shown in Listing 16. In this pseudocode, we assume that the `for` construct can be used to express sequential multidimensional (nested) loops. Unlike Java lambdas, we assume that the non-final values of `i` and `j` in the pseudocode are copied automatically when the `async` is created, thereby avoiding the possibility of data races on `i` and `j`. (There are other programming languages that support this convention, most notably C++11 lambdas with the `=` capture clause.)

The `for` loop in Case 1 expresses a two-dimensional loop with $m \times n$ iterations. Since the body of this loop is an `async` statement, both loops `i` and `j` can run in parallel in Case 1. However, only loop `i` can run in parallel in Case 2, and only loop `j` can run in parallel in Case 3.

Most parallel programming languages include special constructs to embody the commonly used `finish–for–async` parallel loop pattern shown above in Listing 16. Following the notation used in other parallel languages and the `∀` mathematical symbol, we use the `forall` keyword to identify loops with single or multidimensional parallelism and an implicit finish. Listing 17 shows how the loops in Listing 16 can be rewritten using the `forall` notation.

```
// Case 1: loops i, j can run in parallel
finish for (point[i,j] : [0:m-1,0:n-1]) async
    A[i][j] = F(A[i][j]) ;

// Case 2: only loop i can run in parallel
finish for (point[i] : [1:m-1]) async
    for (point[j] : [1:n-1]) // Equivalent to for (j=1;j<n;j++)
        A[i][j] = F(A[i][j-1]) ;

// Case 3: only loop j can run in parallel
for (point[i] : [1:m-1]) // Equivalent to for (i=1;i<m;i++)
    finish for (point[j] : [1:n-1]) async
        A[i][j] = F(A[i-1][j]) ;
```

Listing 16: Examples of three parallel loops using finish-for-async (pseudocode)

```
// Case 1: loops i, j can run in parallel
forall (point[i,j] : [0:m-1,0:n-1]) A[i][j] = F(A[i][j]) ;

// Case 2: only loop i can run in parallel
forall (point[i] : [1:m-1])
    for (point[j] : [1:n-1]) // Equivalent to for (j=1;j<n;j++)
        A[i][j] = F(A[i][j-1]) ;

// Case 3: only loop j can run in parallel
forall (point[i] : [1:m-1]) // Equivalent to for (i=1;i<m;i++)
    forall (point[j] : [1:n-1])
        A[i][j] = F(A[i-1][j]) ;
```

Listing 17: Examples of three parallel loops using forall (pseudocode)
3.2 Parallel Matrix Multiplication

Consider the pseudocode fragment for a parallel matrix multiplication example in Listing 18.

This program executes all \((i,j)\) iterations for line 4 in parallel to initialize array \(C\), waits for all the iterations to complete at line 5, and then executes all \((i,j)\) iterations for lines 10–11 in parallel (each of which executes the \(k\) loop sequentially). Since \(\text{async}\) and \(\text{finish}\) are powerful and general constructs, the structure of sequential and parallel loops in Listing 18 is not immediately easy to discern. Instead, the same program can be rewritten more compactly and clearly using \(\text{forall}\) loops as shown in Listing 19.

There are a number of features worth noting in Listing 19:

- The combination of \(\text{for}\)–\(\text{for}\)–\(\text{async}\) is replaced by a single keyword, \(\text{forall}\). Multiple loops can be collapsed into a single \(\text{forall}\) with a multi-dimensional iteration space. (In Listing refcode:finish-async, both loop nests are two-dimensional.)
- The iteration variable for a \(\text{forall}\) is a \(\text{point}\) (integer tuple) such as \([i,j]\).
- The loop bounds can be specified as a rectangular \(\text{region}\) (dimension ranges) such as \([0:n-1,0:n-1]\).
- We also extend the sequential \(\text{for}\) statement so as to iterate sequentially over a rectangular region, as in line 5.

We now briefly discuss the point and region constructs used in our pseudocode. A \(\text{point}\) is an element of an \(k\)-dimensional Cartesian space \((k \geq 1)\) with integer-valued coordinates, where \(k\) is the rank of the point. A point’s dimensions are numbered from 0 to \(k-1\). Points can be used outside of \(\text{forall}\) loops, if so desired. For completeness, we summarize the following operations that are defined on a point-valued expression \(p1\), even though it is unlikely that you will need to go beyond the use of points shown in Listing 19:

- \(p1.\text{rank}\) — returns rank of point \(p1\)
Listing 20: Unchunked and chunked versions of a forall loop

- p1.get(i) — returns element in dimension i of point p1, or element in dimension (i mod p1.rank) if i < 0 or i ≥ p1.rank.

- p1.lt(p2), p1.le(p2), p1.gt(p2), or p1.ge(p2) returns true if and only if p1 is lexicographically <, ≤, >, or ≥ p2. These operations are only defined when p1.rank = p1.rank.

A k-dimensional region is a set of k-dimensional points, defined as a Cartesian product of low:high contiguous subranges in each dimension. Thus, [1 : 10] is a 1-dimensional region consisting of the 10 points [1,...,10], and [1 : 10, −5 : 5] is a 2-dimensional region consisting of 110 points since the first dimension has 10 values (1,...,10) and the second dimension has 11 values (−5,...,5). Likewise, the region [0:200,1:100] specifies a collection of two-dimensional points (i,j) with i ranging from 0 to 200 and j ranging from 1 to 100. Regions are used to define the range for sequential point-wise for and parallel forall loops.

A task executes a point-wise for statement by sequentially enumerating the points in its region in canonical lexicographic order, and binding the components of the points to the index variables defined in the for statement e.g., variable k in line 3 of Listing 19. A convenience relative to the standard Java idiom, “for (int i = low; i <= high; i++)”, is that the upper bound, high, is re-evaluated in each iteration of a Java loop, but it is only evaluated once in a [low:high] region expression. Another convenience is that loops can be easily converted from sequential to parallel (or vice versa) by replacing for by forall.

Finally, we include a forasync statement that is like forall but does not include an implicit finish statement. The statement forasync (point p : R) S supports parallel iteration over all the points in region R by launching each iteration S as a separate async. Just as with standard async statements, a separate finish construct is needed to await termination of all iterations in a forasync.

3.3 Iteration Grouping: Chunking of Parallel Loops

Though the forall construct is convenient for the programmer, the approach of creating a separate async task for each iteration can lead to excessive overheads. For a parallel loop, there are additional choices available. A natural approach to reduce the overhead of parallel loops is that of batching or “chunking” groups of iterations together so that iterations in the same chunk execute sequentially within a single async task, but parallelism can be exploited across chunks. The chunks size plays a critical role in determining the effectiveness of chunking. If it is too small, then the overhead can still be an issue due to the small size of async tasks. If it is too large, then there is a danger of losing too much parallelism. Fortunately, it is possible to set up chunking of parallel loops such that the number of chunks (or equivalently, the chunk size) can be specified as a runtime parameter that can be “tuned” for a given input size and parallel machine. For loops in which the amount of work per iteration is fixed, a common approach is to set the number of chunks to the number of available processors.
// Return range for chunk ii if range [rLo:rHi] is divided into nc chunks
static region getChunk(int rLo, rHi, int nc, int ii) {
    if (rLo > rHi) return [0:−1]; // Empty region
    assert(nc > 0); // Number of chunks must be > 0
    assert(0 <= ii && ii < c); // ii must be in [0:c−1] range
    int chunkSize = (rHi−rLo+c−1)/c;
    int myLo = rLo + ii∗chunkSize;
    int myHi = Math.min(rHi, rLo + (ii+1)*chunkSize − 1);
    return [myLo:myHi]; // Range for chunk ii
}

// Chunked version using getChunk function
int nc = numWorkerThreads(); // Set number of chunks to number of worker threads
forall (point [ii] : [0:nc−1]) {
    region myRange = getChunk(rLo, rHi, nc, ii);
    int myLo = myRange.rank(0).low();
    int myHi = myRange.rank(0).high();
    for(int i = myLo; i <= myHi; i++)
        X[i] = Y[i] + Z[i];
}

Listing 21: Unchunked and chunked versions of a one-dimensional forall loop

Listing 20 includes unchunked and chunked version of an example forall loop. The chunking is achieved by creating an outer parallel forall loop with number of chunks = nc and an inner sequential for loop that executes the iterations in a given chunk. We assume the availability of a library call, numWorkerThreads(), that returns the number of worker threads with which the parallel program execution was initiated; this is a suitable value for the number of chunks in this example. The size variable is then set to the expected chunk size i.e., number of iterations per chunk. If nc evenly divides n, then we could just set size to equal n/nc. Otherwise, we’d like to set size to be [n/nc]. Since Java does not provide a convenient primitive for performing this operation on integers, we use the mathematical property that \[\lceil x/y \rceil = \lfloor (x + y - 1)/y \rfloor\] for integers x, y such that y > 0. (Recall that standard integer division in languages like Java and C truncates downwards like the floor function.)

After nc and size have been identified, the outer forall loop is set up to execute for nc iterations with index variable ii ranging from 0 to nc − 1. Each forall iteration then computes the range of iterations for its chunk, myLo...myHi as a function of its index variable ii. The use of the Math.min function ensures that the last chunk stays within the bounds of the original loop (in the case that nc does not evenly divide n). This division into chunks guarantees that each iteration of the original loop is assigned to exactly one chunk and that all chunks have the same size when n is a multiple of nc.

The above calculation can get more complicated when the lower bound of the original loop is non-zero, and when the original forall has a multidimensional region. For general loop bounds, we can introduce a helper function called GetChunk() as shown in Listing 21. For multidimensional regions, the GetChunk() function can simply be performed separately in each dimension, provided that the total number of chunks is also given as a multidimensional region that specifies the number of chunks in each dimension.

3.4 Barriers in Parallel Loops

Thus far, you have learned the fundamentals of task creation (async, async await) and task termination (finish, future.get()). There are many algorithms that also need to implement some form of directed synchronization among tasks, with well defined predecessor and successor steps in the computation graph. While

\[Math.ceil()\] only operates on values of type double.
the `finish` and `future.get()` constructs impose directed synchronization, they only apply to cases where the predecessor has to terminate for the synchronization to be enabled (via `join` edges in the computation graph).

To understand the need for other forms of directed synchronization, especially a `barrier` synchronization, consider the simple “Hello-Goodbye” forall example program shown in Listing 22. This example contains a single `forall` loop with \( m \) iterations numbered \( 0 \)...\( m-1 \). The main program task starts execution at line 1, creates \( m \) child tasks at line 2, and waits for them to finish after line 7. (Recall that `forall` is shorthand for `finish–for–async`.) Each `forall` iteration (task) then prints a “Hello” string (line 5) and a “Goodbye” string (line 6). While the Hello and Goodbye strings from the same task must be printed in order, there is no other guarantee on the relative order among print statements from different tasks. For example, the following output is legal for the \( m = 4 \) case:

```
Hello from task ranked 0 with square = 0
Hello from task ranked 1 with square = 1
Goodbye from task ranked 0 with square = 0
Hello from task ranked 2 with square = 4
Goodbye from task ranked 2 with square = 4
Goodbye from task ranked 1 with square = 1
Hello from task ranked 3 with square = 9
Goodbye from task ranked 3 with square = 9
```

Now, let us consider how to modify the program in Listing 22 so as to ensure that all Hello strings are printed before any Goodbye string. One approach would be to replace the `forall` loop by two `forall` loops, one for the Hellos and one for the Goodbyes. However, a major inconvenience with this approach is that all local variables in the first `forall` loop (such as `square`) need to be copied into objects or arrays so that they can be communicated into the second `forall` loop. The preferred approach instead is to use next statements, commonly known as barriers, as shown in Listing 23.

The semantics of a next statement inside a `forall` is as follows. A `forall` iteration \( i \) suspends at next until all iterations arrive (i.e., all iterations complete their previous phase), after which iteration \( i \) can advance to its next phase. Thus, in Listing 23 next acts as a barrier between Phase 0 which corresponds to all the computations executed before next and Phase 1 which corresponds to all the computations executed after next.

Figure 13 illustrates how the barrier synchronization (next statement) works for the program example in Listing 23 for the \( m = 4 \) case. Each task (iteration) performs a `signal` (`sig`) operation when it enters the barrier, and then performs a `wait` (`wait`) operation thereby staying idle until all tasks have entered the barrier. In the scenario shown in Figure 13, iteration \( i = 0 \) is the first to enter the barrier, and has the longest idle time. Iteration \( i = 2 \) is the last to enter the barrier, so it has no idle time since its `SIGNAL` operation releases all iterations waiting at the barrier.

Can you think of real-world situations that can be modeled by barriers? Consider a (somewhat elaborate)

---

6The source of nondeterminism in this example arises from the race conditions among the print statements, which violates the precondition of the Structural Determinism property in Section 2.6.
family meal where no one starts eating the main course until everyone has finished their soup, and no one
starts eating dessert until everyone has finished their main course. In this case, each family member can be
modeled as a forall iteration, each course — soup, main dish, and dessert — can be modeled as a phase,
and each synchronization between phases can be modeled as a barrier.

The next statement in a forall provides its parallel iterations/tasks with a mechanism to periodically
rendezvous with each other. The scope of synchronization for a next statement is its closest enclosing
forall statement. Specifically, when iteration \( i \) of the forall executes next, it is informing the other
iterations that it has completed its current phase and is now waiting for all other iterations to complete
their current phase by executing next. There is no constraint on which statements are executed by a
forall iteration before or after a next statement. There is also no constraint on where a next can be performed
by a forall iteration. For example, a next can be performed by a task in the middle of an if, while or for
statement, and different forall iterations can even perform next at different program points in different
methods.

When a forall iteration \( i \) terminates, it also drops its participation in the barrier i.e., other iterations do
not wait for iteration \( i \) past its termination. This rule avoids the possibility of deadlock with next operations.
The example in Listing 24 illustrates this point.

The iteration numbered \( i \) in the forall-i loop in line 1 of Listing 24 performs a sequential for-j loop in
line 2 with \( i + 1 \) iterations \( (0 \leq j \leq i) \). Each iteration of the for-j loop prints \((i, j)\) before performing a
next operation. Thus, \( j \) captures the phase number for each forall-i iteration participating in the barrier.
Iteration \( i = 0 \) of the forall-i loop prints \((0,0)\), performs a next, and then terminates. Iteration \( i = 1 \) of
the forall-i loop prints \((1,0)\), performs a next, prints \((1,1)\), performs a next, and then terminates. And
so on, as shown in Figure 14 which illustrates how the set of forall iterations synchronizing on the barrier
decreases after each phase in this example.

\[\text{Later, you will learn how the next statement can be used outside forall’s as well.}\]
forall (point[i] : [0:m-1]) {
    for (point[j] : [0:i] {
        // For all iteration i is executing phase j
        System.out.println("(" + i + ", " + j + ")");
        next;
    }
}
Figure 15 shows how a `next` operation can be modeled in the dynamic Computation Graph by adding `signal` and `wait` edges. A_1, A_2, A_3, A_4 represent four iterations in a common `forall` loop. The execution of a `next` statement causes the insertion of a single `next` node in the CG as shown in Figure 15. `signal` edges are added from the last step prior to the `next` in each `forall` iteration to the `next` node, and `wait` edges are added from the `next` node to the continuation of each `forall` iteration. Collectively, these edges enforce the barrier property since all tasks must complete their `Phase j` computations before any task can start its `Phase j+1` computation.

### 3.4.1 Next-with-single Statement

Consider an extension to the Hello-Goodbye program in which we want to print a log message after the Hello phase ends but before the Goodbye phase starts. Though this may sound like a contrived problem, it is representative of logging functionalities in real servers where status information needs to be printed at every “heartbeat”.

A simple solution is to assign this responsibility to iteration i = 0 of the `forall` loop as shown in Listing 25. The log message is printed by iteration i = 0 on line 8 after a barrier in line 7 and before a second barrier in line 9. Though correct, it is undesirable to use two barriers when trying to log a single phase transition. To mitigate this problem, the `next` statement offers a `next-with-single` option. This option has the form `next single (single-statement)`, where `(single-statement)` is a statement that is performed exactly once after all tasks have completed the previous phase and before any task begins its next phase. The CG edges for a `next-with-single` statement are shown in Figure 16.

Listing 26 shows how a `next-with-single` statement can be used to perform the same computation as in Listing 25 by using one barrier operation (with a single statement) instead of two. Note that no `if` statement is needed in the body of the single statement, since it will be executed exactly once by a randomly selected
3.5 One-Dimensional Iterative Averaging

To further motivate the need for barriers, consider the one-dimensional iterative averaging algorithm illustrated in Figure 17. The idea is to initialize a one-dimensional array of double with n+2 elements, myVal, with boundary conditions, myVal[0] = 0 and myVal[n+1] = 1. Then, in each iteration, each interior element (with index in the range 1...n) is replaced by the average of its left and right neighbors. After a sufficient number of iterations, we expect each element of the array to converge to myVal[i] = i/(n+1). For this final quiescent equilibrium state, it is easy to see that myVal[i] = (myVal[i-1] + myVal[i+1])/2 must be the average of its left and right neighbors, for all i in the range 1...n.

3.5.1 Idealized Implementations of One-Dimensional Iterative Averaging Example

In this section, we discuss two idealized implementations of the one-dimensional iterative averaging example. The first version in Listing 27 uses a for–forall structure, whereas the second version in Listing 28 uses a forall–for–next structure.
The first version in Listing 27 contains an outer for–iter loop in line 2 which is intended to run for a sufficiently large number of iterations to guarantee convergence. (Many real-world applications use a while loop instead of a counted for loop to test for convergence.) Each iteration of the for–iter loop starts by allocating and initializing a new output array, myNew, in line 5. For each instance of the forall in lines 6–8, myVal is a reference to the array computed in the previous iteration and myNew is a reference to the array computed in the current iteration. Line 6 performs the averaging step in parallel due to the forall–j loop. There are no data races induced by line 6, since the reads and writes are performed on distinct arrays and each write is performed on a distinct location in myNew.

You learned earlier that repeated execution of forall, as in Listing 27, can incur excessive overhead because each forall spawns multiple async tasks and then waits for them to complete with an implicit finish operation. Keeping this observation in mind, Listing 28 shows an alternate implementation of the iterative averaging example using the next (barrier) statement. Now, the forall loop has moved to the outer level in line 3 and the for loop to the inner level in line 4. Further, the array references myVal and myNew are stored in fields rather than local variables so that they can be updated inside a forall iteration. Finally, a next-with-single statement is used in lines 5–8 to ensure that the “myVal = myNew;” copy statement and the allocation of a new array in lines 6 and 7 are executed exactly once during each phase transition.

### 3.5.2 Optimized Implementation of One-Dimensional Iterative Averaging Example

Though Listing 28 in Section 3.5.1 reduced the number of tasks created by the use of an outer forall with a barrier instead of an inner forall, two major inefficiencies still remain. First, the allocation of a new array in every iteration of the for–iter loop is a major source of memory management overhead. Second, the forall loop creates one task per array element which is too fine-grained for use in practice.

To address the first problem, we observe that only two arrays are needed for each iteration, an input array and an output array. Therefore, we can get by with two arrays for the entire algorithm by just swapping the roles of input and output arrays in every iteration of the for–iter loop. To address the second problem, we can use loop chunking as discussed in Section 3.3. Specifically, the forall loop can be created for t ≪ n.
1 // Assume that myVal and myNew are mutable fields of type double[]
2 myNew = new double[n]; myNew[0] = 0; myNew[n+1] = 1;
3forall (point [j] : [1:n]) { // Create n tasks
4    for (point [iter] : [0:iterations-1]) {
5        // single statement
6            myVal = myNew; // myNew becomes input array for next iteration
7            myNew = new double[n]; myNew[0] = 0; myNew[n+1] = 1;
8        }
9    myNew[j] = (myVal[j-1] + myVal[j+1])/2.0;
10 } // for
11} // forall

Listing 28: One-Dimensional Iterative Averaging Example using forall-for-next-single computation structure

1 double[] val1 = new double[n]; val[0] = 0; val[n+1] = 1;
2 double[] val2 = new double[n];
3int batchSize = CeilDiv(n, t); // Number of elements per task
4forall (point [i] : [0:t-1]) { // Create t tasks
5    double[] myVal = val1; double myNew = val2; double[] temp = null;
6    int start = i*batchSize + 1; int end = Math.min(start+batchSize-1,n);
7    for (point [iter] : [0:iterations-1]) {
8        for (point [j] : [start:end])
9            myNew[j] = (myVal[j-1] + myVal[j+1])/2.0;
10       next; // barrier
11    } // for
12} // forall
13

Listing 29: One-Dimensional Iterative Averaging Example using forall-for-next computation structure with t parallel tasks working on an array with n + 2 elements (each task processes a batch of array elements)

iterations, and each iteration of the forall loop can be responsible for processing a batch of n/t iterations sequentially.

Keeping these observations in mind, Listing 29 shows an alternate implementation of the iterative averaging example. The forall loop is again at the outermost level (line 4), as in Listing 28. However, each iteration of the forall now maintains local variables, myVal and myNew, that point to the two arrays. The swap(myNew, myVal) computation in line 11 swaps the two references so that myNew becomes myVal in the next iteration of the for loop. (There are two distinct array objects allocated in lines 1 and 2, whereas myVal and myNew are pointers to them that are swapped each time line 10 is executed.) Maintaining these pointers in local variables avoids the need for synchronization in the swap computation in line 11.

Line 3 computes batchSize as ⌈n/t⌉. Line 6 computes the start index for batch i, where 0 ≤ i ≤ t – 1. The for loop in line 7 sequentially computes all array elements assigned to batch i. (The Math.min() function is used to ensure that the last iteration of the last batch equals n.) This form of batching is very common in real-world parallel programs. In some cases, the compiler can perform the batching (chunking) transformation automatically, but programmers often perform the batching by hand so as to be sure that it is performed as they expect.

The for-iter loop at line 7 contains a next operation in line 10. The barrier semantics of the next statement ensures that all elements of myNew are computed in line 9 across all tasks, before moving to line 11 and the next iteration of the iter loop at line 8. We can see that only t tasks are created in line 4, and the same
tasks repeatedly execute the iterations of the \texttt{iter} loop in line 7 with a barrier synchronization in line 10.
4 Dataflow Synchronization and Pipelining

4.1 Fuzzy Barriers

Thus far, you have studied the use of `next` as shorthand for `signal` and `wait` operations performed by a task. In fact, the deadlock freedom property for phasers depends on the fact that the programmer does not have the ability to perform a `wait` operation separately from `signal` operations. However, there are some cases when it can be useful to perform a `signal` operation for a given phase ahead of a `next` operation. This idiom is referred to as split-phase barriers or fuzzy barriers [10].

A typical use case of this occurs when a task has a combination of shared work and local work to perform in a given phase. Listing 30 contains a simple example to illustrate this point.

Each of tasks T1 and T2 in Listing 30 contain shared work and local work in phase 0. Task T1 computes a in phase 0 (line 4) whose value is to be shared with task T2 in phase 1 (line 15). Likewise, task T2 computes x in phase 0 (line 11) whose value is to be shared with task T1 in phase 1 (line 8). The use of `next` in lines 7 and 14 provides the necessary synchronization to ensure that this sharing can occur without creating a data race.

However, each of tasks T1 and T2 also have some local work to perform between phases 0 and 1. In the case of T1, it is the computation of b in line 6, and in the case of T2, it is the computation of y in line 13. These local computations can logically be performed before or after the `next` operation, but it would be ideal if they could be performed in parallel with the phase transition. The use of `signal` statements in lines 5 and 12 achieves this desired effect.

When a task T performs a `signal` operation, it notifies all the phasers it is registered on that it has completed all the work expected by other tasks in the current phase (the “shared” work). Since `signal` is a non-blocking operation, an early execution of `signal` cannot create a deadlock. Later on, when T performs a `next` operation, the `next` degenerates to a `wait` since a `signal` has already been performed in the current phase. The execution of “local work” between `signal` and `next` is performed during phase transition; hence the use of names such as “split-phase barrier” and “fuzzy barrier” to describe this concept.

Figure 18 shows the Computation Graph (CG) corresponding to Listing 30. Note that there is a path of dependence edges from statement 4 in task T1 to statement 15 in task T2, but no dependence path from statement 6 in task T1 to statement 15 in task T2. Likewise, there is a path of dependence edges from
Figure 18: Computation Graph for HJ program in Listing 30. Shaded steps 6 and 13 represent local work executed in parallel with phase transition.

statement 11 in task T2 to statement 8 in task T1, but no dependence path from statement 13 in task T2 to statement 8 in task T1. The ability to overlap statements 6 and 13 with the phase transition reduces the overall critical path length of the CG, compared to the case if the signal statements in lines 5 and 12 were removed.

The HJ language provides two utility functions ph.getSigPhase() and ph.getWaitPhase() to indicate which phase a task is in with respect to phaser ph. At the start of phase i, both ph.getSigPhase() and ph.getWaitPhase() will return i. However, if a signal operation is performed before a next, then ph.getSigPhase() returns i + 1 while ph.getWaitPhase() still returns i at any program point between signal and next. After the next, both ph.getSigPhase() and ph.getWaitPhase() will return i + 1. These signal and wait phase numbers can be used to establish the following phase-ordering property, which states how the phase numbers can be used to establish ordering among steps in a Computation Graph.

Phase-ordering property: Given two CG steps S₁ and S₂ in the CG, if there exists a phaser ph such that ph.getSigPhase(S₁) < ph.getWaitPhase(S₂) then there must be a path of dependence edges from S₁ to S₂ in the CG.

As an example, statement 4 in Figure 18 would return ph.getSigPhase() = 0 but statement 6 in Figure 18 would return ph.getSigPhase() = 1. Since statement 15 would return ph.getWaitPhase() = 1, the phase-ordering property guarantees that statement 4 (but not statement 6) must precede statement 15.

The idea of split-phase barriers can be used to further increase the parallelism in the optimized one-dimensional iterative averaging example using point-to-point synchronization in Listing 39. The key observation is that only the boundary elements need to be communicated between tasks in each iteration. Listing 31 shows how the split-phase concept can be combined with point-to-point synchronization. The computations of myNew[start] and myNew[end] have now been “peeled” out in lines 12 and 13, after which the signal operation in line 14 indicates that all shared work has been completed. The computation of interior elements start+1:end-1 is local work and can be overlapped with phase transition by placing the for loop in lines 15 and 16 between the signal (line 14) and next (line 17) operations.
1. \texttt{double}[\ ] val1 = new double[n]; val[0] = 0; val[n+1] = 1;
2. \texttt{double}[\ ] val2 = new double[n];
3. \texttt{int} batchSize = CeilDiv(n, t); // Number of elements per task
4. \texttt{finish} {
5. \texttt{phaser} ph = new phaser[t+2];
6. \texttt{forall (point \ [i]:[0:t+1]) ph[i]=new phaser (phaserMode.SIG,WAIT);};
7. \texttt{for (point \ [i]:[1:t])}
8. \texttt{async phased (ph[i]<SIG>, ph[i-1]<WAIT>, ph[i+1]<WAIT>)} {
9. \texttt{double[] myVal = val1; double myNew = val2; double[] temp = null;}
10. \texttt{int start=(i-1)*batchSize+1; int end=Math.min(start+batchSize-1,n);}
11. \texttt{for (point \ [iter]:[0:iterations-1])} {
12. \texttt{myNew[start] = (myVal[start-1] + myVal[start+1])/2.0;}
13. \texttt{myNew[end] = (myVal[end-1] + myVal[end+1])/2.0;}
14. \texttt{signal; // signal \ ph[i]}
15. \texttt{for (point \ [j]:[start+1:end-1])}
16. \texttt{myNew[j] = (myVal[j-1] + myVal[j+1])/2.0;}
17. \texttt{next; // wait on \ ph[i-1] and \ ph[i+1]}
18. \texttt{temp = myNew; myNew = myVal; myVal = temp; // swap(myNew, myVal)}
19. \texttt{}} // for
20. \texttt{}} // for-async
21. \texttt{}} // finish

Listing 31: Optimized One-Dimensional Iterative Averaging Example using signal statements for split-phase point-to-point synchronization

4.2 Point-to-point Synchronization with Phasers

Your repertoire of fundamental parallel programming constructs now includes task creation (\texttt{async, async await}), task termination (\texttt{finish, future.get()}), and barrier synchronization (\texttt{next in forall} loops). These constructs can all be modeled by a unified Computation Graph in which each node represents a sequential indivisible step, and each (directed) edge represents one of the following cases:

- \textit{Continue edges} capture sequencing of steps within a task.
- \textit{Spawn edges} capture creation of child tasks, as in \texttt{async} and \texttt{forall}.
- \textit{Join edges} capture task termination as in \texttt{finish} and \texttt{future.get()}.
- \textit{Signal and wait edges} capture directed synchronization as in the \texttt{next} statement.

While barrier synchronization is an important special case of directed synchronization, there are are many other synchronization patterns that can be expressed using \texttt{signal} and \texttt{wait} edges in a Computation Graph including nearest-neighbor synchronization and pipeline parallelism. These patterns build on the idea of point-to-point synchronization between two tasks that date back to the concept of binary semaphores.\footnote{When you learn about semaphores in an Operating Systems class, you can relate them to this class by thinking of semaphores as lower-level OS mechanisms that can be used to implement programming constructs such as \texttt{finish, future.get()}, \texttt{isolated}, and \texttt{next}.}

As one example of point-to-point synchronization, consider the following parallel loop expressed using the expanded \texttt{finish-for-async} notation rather than a \texttt{forall}. (The reason for the expansion will become clear later.) Each iteration \(i\) of the parallel loop in Listing 32 performs two method calls in sequence, \texttt{doPhase1(i)} and \texttt{doPhase2(i)}. Earlier, you learned how to insert a \texttt{next} statement in a \texttt{forall} loop to implement a barrier. Now, consider a less constrained case when iteration \(i\) only needs to wait for iterations \(i-1\) and \(i+1\) to complete their work in \texttt{doPhase1()} before it starts \texttt{doPhase2(i)} i.e., iteration \(i\) only needs to synchronize on its left neighbor and right neighbor.
Listing 32: A simple parallel loop

```
finish {
    for (point [i] : [1:m])
        async {
            doPhase1(i);
            doPhase2(i);
        }
}
```

Figure 19: Illustration of left-neighbor right-neighbor point-to-point synchronization in a loop like Listing 32, assuming \( m = 8 \)

Figure 19 illustrates this synchronization pattern. Since it is different from a barrier, you will learn how the necessary point-to-point synchronization can be implemented using the more general phaser construct. Note the boundary conditions in Figure 19 where iteration \( i = 1 \) only needs to wait for iteration \( i + 1 = 2 \) to complete \( \text{doPhase1()} \), and iteration \( i = m - 1 = 8 \) only needs to wait for iteration \( i = m - 1 = 7 \) to complete \( \text{doPhase1()} \). Continuing the dining analogy discussed earlier for barriers, we can think of this synchronization as enforcing a rule that you cannot advance to your next course (Phase 2) until the neighbors on your left and right have completed their previous course (Phase 1), which is a less stringent requirement than a barrier between the two phases.

The previous examples motivated the need for point-to-point synchronization in multiple scenarios. We now introduce phasers [17]. Phasers were added to the HJ language as an extension to the clock construct developed in the X10 language [5]. A limited version of phasers was also added to the Java 7 `java.util.concurrent.Phase` library [15]. A phaser is a special kind of synchronization object that unifies point-to-point and barrier synchronization in a single construct, while supporting dynamic parallelism i.e., the ability for tasks to drop phaser registrations and for new tasks to add new phaser registrations.

Each async task has the option of registering with a phaser in `signal-only` (signal) or `wait-only` mode for point-to-point synchronization or `signal-wait` mode for barrier synchronization. As with barriers, a `next` statement is used to advance each phaser that a task is registered on (according to the registration modes), and the `next` statement can optionally include a `single` statement which is guaranteed to be executed exactly once during a phase transition. The `forall` barrier synchronization that you learned earlier is actually implemented by allocating an implicit phaser for each `forall` instance, and registering all `forall` iterations on that phaser in `signal-wait` mode.

At any point in time, a task can be registered in one of four modes with respect to a phaser: `SINGLE`, `signal-wait`, `signal-only`, or `wait-only`. The mode defines the set of capabilities — `signal`, `wait`, `single` — that the task has with respect to the phaser. The subset relationship defines a natural hierarchy of the registration modes, as shown in Figure 20. Thus, `signal-wait` mode is above `signal-only` and `wait-only` modes in the hierarchy because the capability set for registration mode `signal-wait` is \{`signal`, `wait`\} and the capability sets for `signal-only` and `wait-only` are \{`signal`\} and \{`wait`\} respectively.

The four primary phaser operations that can be performed by a task, \( A_i \), are defined as follows. You will learn some additional (advanced) phaser operations later in the course:
1. **new**: When \( A_i \) performs a new phaser\((\text{MODE})\) operation, it results in the creation of a new phaser, \( ph \), such that \( A_i \) is registered with \( ph \) according to \( \text{MODE} \). If \( \text{MODE} \) is omitted, the default mode assumed is \( \text{signal-wait} \). Phaser creation also initializes the phaser to its first phase (phase 0). At this point, \( A_i \) is the only task registered on \( ph \). Additional descendant tasks of \( A_i \) can add registrations on \( ph \), using the async phased construct described in item 2. The scope of the phaser is limited to the Immediately Enclosing Finish (IEF) for the new statement.

2. **phased async**: \( \text{async phased} ( \langle \text{mode}_1 \rangle, \ldots ) A_j \)

   When task \( A_i \) creates an async child task \( A_j \), it has the option of registering \( A_j \) with any subset of phaser capabilities possessed by \( A_i \). This subset is specified by the registration mode (\( \text{mode}_k \) for phaser \( ph_k \)) contained in the phased clause. We also permit the “async phased \( A_j \)” syntax as shorthand to indicate that \( A_i \) is transmitting all its capabilities on all phasers that it is registered with to \( A_j \).

   The subset rule is also referred to as the Capability Rule for phasers i.e., a child task can only inherit a subset of its parent task’s phaser capabilities. However, it can add new capabilities by creating new phasers in its scope.

3. **drop**: \( A_i \) implicitly drops its registration on all phasers when it terminates. In addition, when \( A_i \) executes an end-finish instruction for finish statement \( F \), it implicitly de-registers from each phaser \( ph \) for which \( F \) is the Immediately Enclosing Finish (IEF) for \( ph \)'s creation. Finally, any task \( A_i \) can explicitly de-register from phaser \( ph \) by executing \( ph\text{.drop()} \).

4. **next**: The next operation has the effect of advancing each phaser on which \( A_i \) is registered to its next phase, thereby synchronizing all tasks registered on the same phaser. As described in 17, the semantics of next depends on the registration mode that \( A_i \) has with a specific phaser, \( ph \).

Listing 33 contains a simple example to illustrate these concepts. A single phaser, \( ph \) is allocated in line 2, and its IEF is the finish statement that spans lines 1–7. Four async tasks are created in lines 3–6 with different registration modes defined by their phased clauses. Figure 21 illustrates these concepts by showing the actions performed by the next statements in tasks \( A_1 \ldots A_4 \) as Computation Graph edges. The unification of point-to-point synchronization can be seen in the fact that tasks \( A_2 \) and \( A_3 \) perform barrier (signal-wait) operations at each next statement, whereas tasks \( A_1 \) and \( A_4 \) perform point-to-point synchronizations.

Let us now revisit the example in Listing 32 and first consider the simple case when \( m = 3 \). Listing 34 shows the use of phasers to ensure proper synchronization for the \( m = 3 \) case. The synchronizations enforced by the phasers \( ph_1 \), \( ph_2 \), and \( ph_3 \) match the pattern in Figure 19 including the boundary conditions for \( i = 1 \) and \( i = 3 \), which need to wait on one phaser each. This code could also have been written by creating separate future async tasks for method calls doPhase1() and doPhase2(), and by using future.get() operations instead of next. However, doing so would incur the same overheads and inconveniences discussed earlier for replacing barriers by finish-async constructs.

This idea can be extended to general values of \( m \) by using the code in Listing 35. Lines 2 and 3 allocate and initialize a phaser array. This makes it convenient to specify the phaser registrations as a function of \( i \) in the...
Listing 33: Simple example with four async tasks and one phaser

```
finish {
    ph = new phaser(); // Default mode is SIG_WAIT
    async phased(ph<SIG>){doA1Phase1(); next; doA1Phase2();} // A1 (SIG mode)
    async phased({doA2Phase1(); next; doA2Phase2();} // A2 (SIG_WAIT mode)
    async phased({doA3Phase1(); next; doA3Phase2();} // A3 (SIG_WAIT mode)
    async phased(ph<WAIT>){doA4Phase1(); next; doA4Phase2();} // A4 (WAIT mode)
}
```

Semantics of next depends on registration mode

- **SIG_WAIT**: next = signal + wait
- **SIG**: next = signal
- **WAIT**: next = wait

A master thread (worker) gathers all signals and broadcasts a barrier completion.

Figure 21: “next” actions performed by tasks with different registration modes on the same phaser.

Listing 34: Extension of example in Listing 32 with three phasers for $m = 3$

```
finish {
    phaser ph1 = new phaser(); // Default mode is SIG_WAIT
    phaser ph2 = new phaser(); // Default mode is SIG_WAIT
    phaser ph3 = new phaser(); // Default mode is SIG_WAIT
    async phased((ph1<SIG>, ph2<WAIT>){ // i = 1
        doPhase1(1);
        next; // Signals ph1, and waits on ph2
        doPhase2(1);
    }
    async phased((ph2<SIG>, ph1<WAIT>, ph3<WAIT>){ // i = 2
        doPhase1(2);
        next; // Signals ph2, and waits on ph1 and ph3
        doPhase2(2);
    }
    async phased((ph3<SIG>, ph2<WAIT>){ // i = 3
        doPhase1(3);
        next; // Signals ph3, and waits on ph2
        doPhase2(3);
    }
}
```
phased clause in line 5. No special case if conditions need to be specified for the boundary cases of \( i = 1 \) and \( i = m \), since the general formulation works correctly in those cases too. For example, the async task for iteration \( i = 1 \) waits on phaser \( ph[0] \). However, no task is registered with a signal capability on \( ph[0] \), so this wait is essentially a no-op. Listing 35 also illustrates the use of a phased clause with a forasync construct.

In summary, phasers are general synchronization constructs that can be used to create complex synchronization patterns specified by phased clauses in async constructs. A task can be registered on multiple phasers in different modes, and a phaser can have multiple tasks registered on it. The use of a next statement, instead of individual signal and wait operations, ensures that each task performs the correct synchronization at the end of each phase. Further, since the expansion of next into signal and wait operations is performed by the compiler and runtime, it is not possible for the programmer to create a deadlock cycle with phasers.

Adding Phaser Operations to the Computation Graph

You have already learned how to define Computation Graphs for HJ programs that use async, finish, and future.get() operations. We now add Computation Graph rules for signal, wait, next and drop phaser operations.

Recall that a Computation Graph (CG) node represents a step consisting of an arbitrary sequential computation, and that a task’s execution is divided into steps by using continuations to define the boundary points. The set of operations that induce continuation points includes async (source of a spawn edge), end of a finish statement (destination of join edges), future.get() (destination of a join edge), signal and drop (source of signal edges), wait (destination of wait edges), and next (source of signal edges and destination of wait edges). As discussed earlier, it is acceptable to introduce finer-grained steps in the CG if so desired i.e., to split a step into smaller steps than the boundaries induced by continuation points. The key constraint is that a continuation point should not be internal to a step.

Each next operation performed by a task is modeled as two steps, signal and wait, in the task. Likewise, each end-finish operation is modeled as two steps, drop (to drop all phaser registrations in the finish scope) and end-finish. For convenience, we assume that the CG also includes an unbounded set of pairs of phase transition CG nodes, \( ph.next-start(i \rightarrow i + 1) \) and \( ph.next-end(i \rightarrow i + 1) \), for each phaser \( ph \) allocated during program execution that transitions from phase \( i \) to phase \( i + 1 \).

Given a set of CG nodes, the following classes of CG edges enforce ordering constraints among the nodes:

1. **Continue** edges capture sequencing of steps within a task — all steps within the same task are connected by a chain of continue edges. In addition, each pair of phase transition CG nodes, \( ph.next-start(i \rightarrow i + 1) \) and \( ph.next-end(i \rightarrow i + 1) \), is connected by a continue edge.

2. **Spawn** edges connect parent tasks to child async tasks. When an async is created, a spawn edge is inserted between the step that ends with the async in the parent task and the step that starts the async body in the new child task.
3. Join edges connect descendant tasks to their Immediately Enclosing Finish (IEF) operations and to 
get() operations for future tasks. When an async terminates, a join edge is inserted from the last step in 
the async to the step in the ancestor task that follows the IEF operation. If the async represents 
a future task, then a join edge is also inserted from the last step in the async to each step that starts 
with a get() operation on that future.

4. Signal edges connect each signal or drop operation performed by a task to the phase transition node, 
ph.next-start(i → i + 1), for each phaser ph that the task is registered on with signal capability when 
that phaser is transitioning from phase i to phase i + 1.

5. Wait edges connect each phase transition node, ph.next-end(i → i + 1) to a wait or next operation 
performed by a task, for each phaser ph that the task is registered on with wait capability when that 
phaser is transitioning from phase i to phase i + 1.

6. Single edges connect each phase transition node, ph.next-start(i → i + 1) to the start of a single 
statement instance in a task registered on phaser ph with single capability when that phaser is transitioning 
from phase i to phase i + 1, and the end of that single statement to the phase transition node, 
ph.next-end(i → i + 1).

Let us now revisit the code in Listing 36 which shows the use of phasers to ensure proper synchronization for 
the m = 3 case of the left-right neighbor synchronization example studied earlier. The computation graph 
for this program is shown in Figure 22. The steps in Figure 22 are labeled with statement numbers from 
Listing 36. The spawn, continue and join edges capture the basic finish-async structure of the program 
as before. The new CG nodes include phaser transition nodes (e.g., ph1.next-start(0 → 1) and ph1.next-
end(0 → 1)) and the expansion of next statements into signal and wait nodes (e.g., the next operation 
line 12 is expanded into two CG nodes, 12-signal and 12-wait). The new CG edges are the signal (green) 
and wait (red) edges corresponding to phaser operations. For example, a signal edge is added from the 
12-signal node to the ph2.next-start(0 → 1) node because task T2 is registered on phaser ph2 in signal 
node. Likewise, wait edges are added from the ph1.next-end(0 → 1) and ph3.next-end(0 → 1) nodes to the 
12-wait node because task T2 is registered on phasers ph1 and ph3 in wait mode. Finally, end-finish 
statement 20 is expanded into two CG nodes, 20-drop and 20-end-finish. The signal edges from 20-drop 
to the three ph.next-start(0 → 1) nodes models the synchronization that occurs with the parent task on 
next operations. The 20-end-finish nodes serves as the destination for join edges as before. Note that this 
splitting of an end-finish statement into two CG nodes avoids the creation of a cycle in the CG.

Barriers in Forall Statements revisited Earlier, you learned the use of next as a barrier statement 
in forall loops with examples such as the one in Listing 23. However, now that you have learned the use of 
phaser operations in their full generality, the forall barrier can be understood as an implicit phaser 
allocated as part of a forall statement. Specifically, the HJ programming model implements a forall 
as the finish-for-async-phased code structure shown in Listing 37 with the allocation of a phaser, ph, that 
is not visible to the programmer. Recall that the default convention for async phased is that each child 
task inherits the same phaser registrations as its parent i.e., SIG_WAIT registration on ph in this case. Even 
though both Listing 23 and Listing 37 are equivalent, it is recommended that you use the forall barrier 
version (Listing 23) whenever possible because of its simplicity. The phaser version (Listing 37) should be 
used only when more general synchronization patterns are needed.

4.3 One-Dimensional Iterative Averaging Example with Point-to-Point Synchronization

Listing 38 shows the optimized implementation of the One-Dimensional Iterative Averaging Example with 
a forall loop and barrier (next) operations. The first optimization implemented in this version is batching 
so that only t tasks (forall iterations) are created, and each task sequentially executes iterations start:end 
in its batch (line 8). The second optimization is the reuse of two arrays instead of allocating a new array in 
each iteration of the for-iter loop in lines 7–12.
```java
finish {
    phaser ph1 = new phaser(phaserMode.SIG_WAIT);
    phaser ph2 = new phaser(phaserMode.SIG_WAIT);
    phaser ph3 = new phaser(phaserMode.SIG_WAIT);
    async phased(ph1<phaserMode.SIG>, ph2<phaserMode.WAIT>)
    {
        doPhase1(1); // Task T1
        next; // Signals ph1, and waits on ph2
        doPhase2(1);
    }
    async phased(ph2<phaserMode.SIG>, ph1<phaserMode.WAIT>, ph3<phaserMode.WAIT>)
    {
        doPhase1(2); // Task T2
        next; // Signals ph2, and waits on ph1 and ph3
        doPhase2(2);
    }
    async phased(ph3<phaserMode.SIG>, ph2<phaserMode.WAIT>)
    {
        doPhase1(3); // Task T3
        next; // Signals ph3, and waits on ph2
        doPhase2(3);
    }
} // finish
```

Listing 36: Example of left-right neighbor synchronization for $m = 3$ case

![Computation Graph for example HJ program in Listing 36](image-url)
rank.count = 0; // rank object contains an int field, count
finish {
    phaser ph = new phaser(phaserMode.SIG_WAIT);
    for (point[i] : [0:m-1]) async phased {
        // Start of phase 0
        int square = i*i;
        System.out.println("Hello from task " + i + " with square = " + square);
        next; // Acts as barrier between phases 0 and 1
        // Start of phase 1
        System.out.println("Goodbye from task " + i + " with square = " + square);
    } // for async phased
} // finish

Listing 37: Translation of Listing 23 to a finish-for-async-phased code structure (phaser version)

double[] val1 = new double[n]; val[0] = 0; val[n+1] = 1;
double[] val2 = new double[n];
int batchSize = CeilDiv(n, t); // Number of elements per task
forall (point[i] : [0:t-1]) { // Create t tasks
    double[] myVal = val1; double myNew = val2; double[] temp = null;
    int start=i*batchSize+1; int end=Math.min(start+batchSize-1,n);
    for (point[iter] : [0:iterations-1]) {
        for (point[j] : [start:end])
            myNew[j] = (myVal[j-1] + myVal[j+1])/2.0;
        next; // barrier
        temp = myNew; myNew = myVal; myVal = temp; // swap(myNew, myVal)
    } // for
} // forall

Listing 38: Optimized One-Dimensional Iterative Averaging Example using forall-for-next computation structure with t parallel tasks working on an array with n + 2 elements (each task processes a batch of array elements)

Figure 23: Synchronization structure of HJ program in Listing 38 (red line indicates barrier in line 10, and black arrows indicate actual dependences)

Figure 24: Synchronization structure of HJ program in Listing 39 (blue lines indicate point-to-point phaser synchronization, and black arrows indicate actual dependences)
1. \texttt{double[]} val1 = new double[n]; val[0] = 0; val[n+1] = 1;
2. \texttt{double[]} val2 = new double[n];
3. \texttt{int} batchSize = \texttt{CeilDiv}(n, t); // Number of elements per task
4. \texttt{finish} {
5. \hspace{1em} phaser ph = new phaser[t+2];
6. \hspace{1em} forall (\texttt{point}[i]:[0:t+1]) ph[i] = new phaser(phaserMode.SIG_WAIT);
7. \hspace{1em} for (\texttt{point}[i]:[1:t])
8. \hspace{2em} async phased (ph[i]<SIG>, ph[i-1]<WAIT>, ph[i+1]<WAIT>) {
9. \hspace{3em} double[] myVal = val1; \hspace{2em} double myNew = val2; \hspace{2em} double[] temp = null;
10. \hspace{3em} int start = (i-1)*batchSize + 1; \hspace{2em} int end = Math.min(start+batchSize-1,n);
11. \hspace{3em} for (\texttt{point}[iter]:[0:iterations-1]) {
12. \hspace{4em} for (\texttt{point}[j]:[start:end])
13. \hspace{5em} myNew[j] = (myVal[j-1] + myVal[j+1])/2.0;
14. \hspace{5em} next; \hspace{2em} // signal ph[i] and wait on ph[i-1] and ph[i+1]
15. \hspace{5em} temp = myNew; myNew = myVal; myVal = temp; \hspace{2em} // swap(myNew, myVal)
16. \hspace{4em} } // for
17. \hspace{3em} } // for-async
18. \hspace{1em} } // finish

Listing 39: Optimized One-Dimensional Iterative Averaging Example using point-to-point synchronization, instead of barrier synchronization as in Listing 38

Figure 23 shows the synchronization structure for this example, where the red line indicates the barrier operation and the black arrows indicate the actual dependences in the algorithm that need to be satisfied across successive iterations of the \texttt{for}-\texttt{iter} loop in lines 7–12. As can be seen in Figure 23, the use of a barrier is overkill since the algorithm only needs left-right neighbor synchronization for correctness. Instead, the only synchronizations needed are the ones shown in blue lines in Figure 24. This can be accomplished using point-to-point synchronization with an array of phasers as shown in Listing 39. Note that the synchronization structure in this example is identical to that of the left-right neighbor synchronization studied earlier.

4.4 Pipeline Parallelism

As another example of point-to-point synchronization, consider a one-dimensional pipeline of tasks (stages), \( P_0, P_1, \ldots \), as shown in Figure 25. Pipelines occur in multiple domains e.g., automobile manufacturing assembly lines and image processing pipelines. Figure 26 shows a pipeline used for seismic images that consists of three stages — simulation, rendering, and formatting. The seismic simulation in the first stage generates a sequence of results, one per \textit{time step}. The rendering application in the second stage takes as input the simulation results for one time step, and generates an image for that time step. Finally, the formatting application in the third stage takes the image as input and outputs it into an animation sequence. Even though the processing is sequential for a single time step, pipeline parallelism can be exploited via point-to-point synchronization between neighboring stages so as to enable multiple stages to process different data items in a coordinated way.

This general idea can be seen in the timing diagram in Figure 27 which illustrates the scheduling of data items on pipeline stages, using the notation from Figure 25. The horizontal axis shows the progress of time from left to right, and the vertical axis shows which data item is being processed by which pipeline stage at a given time. Assuming that the inputs \( d_0, d_1, \ldots \) arrive sequentially, pipeline parallelism can be exploited by enabling task (stage) \( P_i \) to work on item \( d_{k-i} \) when task (stage) \( P_0 \) is working on item \( d_k \).

We can undertake a simplified analysis of the timing diagram in Figure 27 assuming that each stage takes 1 unit of time to process a single data item. Let \( n \) be the number of input items and \( p \) the number of stages in the pipeline (\( n = p = 10 \) in Figure 27). Then, \( WORK = n \times p \) is the total work that must be done for all data items, and \( CPL = n + p - 1 \) is the \textit{critical path length} of the pipeline schedule shown in Figure 27. Thus, the ideal parallelism is \( PAR = WORK/CPL = np/(n + p - 1) \).
This formula can be validated by considering a few boundary cases. When \( p = 1 \), the ideal parallelism degenerates to \( PAR = 1 \), which confirms that the computation is sequential when only one stage is available. Likewise, when \( n = 1 \), the ideal parallelism again degenerates to \( PAR = 1 \), which confirms that the computation is sequential when only one data item is available. When \( n \) is much larger than \( p \) (\( n \gg p \)), then the ideal parallelism approaches \( PAR = p \) in the limit, which is the best possible case. Finally, when \( n = p \), then the ideal parallelism becomes \( p/(2 - 1/p) \), which approaches \( PAR = p/2 \), when \( n = p \) is \( \gg 1 \).

In summary, assuming that the number of stages, \( p \), is fixed, the ideal parallelism, \( PAR \), increases with an increasing number of data items. \( PAR \) starts with a degenerate value of 1 when \( n = 1 \), increases to approximately \( p/2 \) when \( n = p \) and approaches \( p \) as \( n \) increases further. This analysis will need to be refined for more realistic scenarios (such as the seismic imaging pipeline in Figure 26) when different stages take different amounts of time. Also, pipelines can be multidimensional *e.g.*, in a two-dimensional pipeline, a stage may receive inputs from both the stage to its west and the stage to its north.

4.5 Data-Driven Futures and Data-Driven Tasks

Data-Driven Futures [18] are an extension of future objects in HJ that support the dataflow model. This extension is enabled by adding an `await` clause to the async statement to create a Data-Driven Task as follows:

```
async await (DDF_a, DDF_b, ...) { statement }
```

Each of $DDF_a, DDF_b, \cdots$ is an instance of the standard `DataDrivenFuture` class in HJ. A DDF acts as a container for a single-assignment value, like regular `future` objects. However, unlike `future` objects, DDF’s can be used in an `await` clause, and any async task can be a potential producer for a DDF (though only one task can be the actual producer at runtime because of the single-assignment property).

Specifically, the following rules apply to `DataDrivenFuture` objects:

- A variable of type `DataDrivenFuture` is a reference to a DDF object. Unlike regular future objects, there is no requirement that variables of type `DataDrivenFuture` be declared with a `final` modifier.
- The following four operations can be performed on variables of type `DataDrivenFuture`:
  1. **Create** — an instance of a DDF container can be created using the standard Java statement, `new DataDrivenFuture()`.
  2. **Produce** — any task can provide a value, $V$, for a DDF container by performing the operation, `DDF.put(V)`. After the `put` operation, the DDF’s value is said to become `available`. If another `put` operation is attempted on the same DDF, the second `put` will throw an exception because of its violation of the single-assignment rule.
  3. **Await** — a new async task can be created with an `await` clause, `await (DDF_a, DDF_b, \cdots)`. The task will only start execution after all the DDFs in the `await` clause become available.
  4. **Consume** — any task that contains a DDF in its `await` clause is permitted to perform a `get()` operation on the DDF. A `cast` operation will be required to cast the result of `get()` to the expected object type. If a `get()` operation is attempted by a task that has no `await` clause or does not contain the DDF in its `await` clause, then the `get()` will throw an exception. Thus, a `get()` on a DDF will never lead to a blocking operation (unlike a `get()` on a regular `future` object).
- It is possible for an instance of an async with an `await` clause to never be enabled, if one of its input DDF never becomes available. This can be viewed as a special case of deadlock.

**Example**

The example HJ code fragment in Figure 28 shows five logically parallel tasks and how they are synchronized through DDFs. Initially, two DDFs are created as containers for data items `left` and `right`. Then a `finish` is created with five async tasks. The tasks, `leftReader` and `rightReader`, include `left` or `right` in their `await` clauses respectively. The fifth task, `bothReader`, includes both `left` and `right` in its `await` clause. Regardless of the underlying scheduler, the first two asyncs are guaranteed to execute before the fifth async.

The computation graph for the five tasks in Figure 28 can be seen in the left side of Figure 30. This exact graph structure cannot be created with pure async and finish constructs without futures or DDFs. Instead, an approximate version with extra dependences can be created using async and finish, as shown in Figure 29 (for which the computation graph can be seen in the right side of Figure 30).

**Implementing regular Future Tasks using Data-Driven Futures**

To further understand Data-Driven Futures, we show how regular future tasks can be implemented using DDFs. Consider the example Habanero Java future construct shown in Figure 31. It can be rewritten to use DDFs, as shown in Figure 32. Once the DDF gets created, it will await the availability of the $f$ object, if it has not been produced yet. The execution of that DDF will thus be delayed until $f$ becomes available.
DataDrivenFuture left = new DataDrivenFuture();
DataDrivenFuture right = new DataDrivenFuture();
finish { // begin parallel region
    async left.put(leftBuilder());  // Task1
    async right.put(rightBuilder()); // Task2
    async await (left) leftReader(left.get()); // Task3
    async await (right) rightReader(right.get()); // Task4
    async await (left, right) bothReader(left.get(), right.get()); // Task5
} // end parallel region

Object left = new Object();
Object right = new Object();
finish { // begin region
    async left = leftBuilder();  // Task1
    async right = rightBuilder(); // Task2
} // end region
finish { // begin region
    async leftReader(left); // Task3
    async rightReader(right); // Task4
    async bothReader(left, right); { // Task5
} // end region

### Listing 40: HJ code to generate Computation Graph $G_3$ using DDFs

```java
finish {
    DataDrivenFuture<Void> ddfA = new DataDrivenFuture<Void>();
    DataDrivenFuture<Void> ddfB = new DataDrivenFuture<Void>();
    DataDrivenFuture<Void> ddfC = new DataDrivenFuture<Void>();
    DataDrivenFuture<Void> ddfD = new DataDrivenFuture<Void>();
    DataDrivenFuture<Void> ddfE = new DataDrivenFuture<Void>();

    async {} . . . ; ddfA.put(); } // Task A
    async await(ddfA) {} . . . ; ddfB.put(); } // Task B
    async await(ddfA) {} . . . ; ddfC.put(); } // Task C
    async await(ddfB, ddfC) {} . . . ; ddfD.put(); } // Task D
    async await(ddfC) {} . . . ; ddfE.put(); } // Task E
    async await(ddfD, ddfE) {} . . . } // Task F
} // finish
```

#### Data-Driven Futures with empty objects

In Section 2.1.4, you learned how the `future<void>` type can be used to create `future async` tasks with a `void` return type. Likewise, a DataDrivenFuture<Void> can be used when a DDF is just intended for synchronization rather than communicating a value. (Actually, any object can be used, since no `get()` operation will be performed on such a DDF.)

Listing 40 shows the HJ code that can be used to generate computation graph $G_3$ in Figure 9 with DDFs. This code uses DDFs without `get()` operations, and provides a systematic way of converting any Computation Graph into an HJ program. The difference between the regular `future` version studied in Section 2.1.1 and this version is that the `async` tasks in Listing 40 will never be started till all their input DDFs become available.
A Abstract vs. Real Performance

Thus far in the course, we have lived in a “Neverland” where parallel programs never run slower than their sequential counterparts, if their performance is measured using idealized abstract performance metrics. However, in the real world, there are a number of overheads that can cause a parallel program to run slower than their sequential counterparts even when they have abundant amounts of parallelism. Here are some of the overheads that are encountered in practice for the constructs that you have studied so far:

**Spawn overhead** When an `async` construct is executed (the source of a `spawn` edge in the computation graph) there is extra book-keeping work that needs to be performed by the parent task to create necessary data structures for the child task. This extra work is referred to as *spawn overhead*, and it is incurred sequentially for each child task spawned by the same parent task. There is also overhead incurred when the child task begins execution, but that overhead can be incurred in parallel when different child tasks are executed by different workers.

**Join overhead** When a task `T_C` terminates (the source of a `join` edge in the computation graph) there is some overhead incurred to check if it is the last task in its Immediately Enclosing Finish (IEF) to terminate. If so, the worker thread executing `T_C` will switch tasks after `T_C` terminates, and resume execution of the ancestor task containing `IEF(T_C)` which involves additional context switching overhead. If not, nothing further needs to be done and `T_C`’s worker can look for other work after `T_C` terminates. If `T_C` is a *future task* then additional overhead is incurred to process any pending `get()` operations on the future.

**IEF-Join overhead** When the end of a `finish` construct `F` is encountered (the sink of a `join` edge in the computation graph) there is some overhead incurred to check if all tasks with `IEF = F` have terminated. If so, nothing further needs to be done. If not, additional overhead is incurred by the worker executing `F` to suspend the current task at the end of `F`, and to look for other work instead (another instance of context switching overhead).

A.1 Work-sharing vs. Work-stealing schedulers

Earlier in the course, you learned that the Habanero-Java (HJ) runtime system is responsible for scheduling unbounded numbers of `async` tasks on a fixed number of processors. It does so by creating a fixed number of *worker threads* as shown in Figure 3, typically one worker per processor core. (This approach is used by many other task-parallel programming models.) These workers repeatedly pull work from a logical work queue when they are idle, and push work on the queue when they generate more work. The work queue entries can include `async`’s and continuations (Section 1.1.1). Work-sharing and work-stealing are two task scheduling paradigms for task parallelism. In work-sharing, when a new task is created, the creator works eagerly to share the task with other worker. This task redistribution is usually implemented by a centralized task queue a shown in Figure 3. A key limitation with
the work-sharing approach is that accesses to the task queue by multiple workers need to be synchronized by the scheduler to avoid race conditions. This centralized task queue can become a scalability bottleneck when the number of workers increases, or when many fine-grain tasks are created. (Remember Amdahl’s Law.) **Work-sharing is the default scheduling paradigm used in HJ** since it supports all the parallel constructs in the language.

In contrast, the **work-stealing paradigm** is implemented using distributed task queues, as shown in Figure 33. Each worker just adds work (tasks) to its own queue when new work is created. An idle worker then selects a “victim” worker to “steal” work from. If it doesn’t obtain any work from its first choice of victim, it then attempts to steal work from another victim worker. Note that the time spent by the idle worker looking for work when no spare work is available will not add to the critical path length (CPL) of the program execution. (Why?) This is one of the reasons why work-stealing is more efficient than work-sharing.

In classical work stealing [3], when a task $\Gamma_a$ spawns task $\Gamma_b$, the worker that spawns $\Gamma_b$ will start to work on $\Gamma_b$ eagerly, and the continuation of $\Gamma_a$ after the spawn might be stolen by other idle workers. This strategy is called the **work-first task scheduling policy** in the work-stealing paradigm. As the alternative, the worker can stay with $\Gamma_a$ and let another worker help by stealing $\Gamma_b$. The worker will work on $\Gamma_b$ later if $\Gamma_b$ is not picked up by other workers. This alternative work-stealing strategy is called the **help-first task scheduling policy**.

The naming of the “work-first” and “help-first” policies can be understood from the perspective of the worker of the parent task when executing an `async`. Under the work-first policy, the parent task’s worker will work on the child task first. Under the help-first policy, the parent task’s worker will ask other workers to help execute the child task first. The work-first policy is sometimes referred to as a **depth-first** policy because, in a 1-worker execution, all the tasks will be executed in the order of depth-first traversal of the task spawn tree. Figure 34 shows a task spawn tree and the 1-thread execution order of the tasks under the work-first policy and the help-first policy.

The work-stealing paradigm with **work-first policy** can be enabled by using the **“hjc -rt w” option** when compiling HJ programs, whereas work-stealing with the **help-first policy** can be enabled by using the **“hjc -rt h” option**. However, the current implementation of the work-stealing paradigm does not support all parallel constructs in the language; notably, it does not support future tasks, data-driven tasks and phasers.

**A.2 Modeling and Measurement of Overhead**

In this section, we use microbenchmarks to model and measure some of the overheads described earlier. A convenient way to measure some of these overheads is to execute a parallel program on a single worker and compare the execution time with that of the sequential counterpart of the parallel program (if one is available).
synchronization cost \( t \) where \( k \) is a function of execution incurs no context switch. Thus, the single worker execution time of the whole microbenchmark as \( k \) tasks are performed asynchronously and task 0 is performed serially. Under the work-first policy, the single worker \( k \) tasks created in the finish scope will be completed and the worker will just continue execution. In the non-trivial case, the current serial execution flow will be interrupted, and a context switch is performed before executing new tasks. We use \( t_{sf} \) to denote the overhead of non-trivial task synchronization. The overhead of the trivial case is considered to be included in \( t_0 \). A similar analysis can be performed for \( \text{get()} \) operations on future tasks, which are omitted for simplicity.

Consider the HJ microbenchmark shown in Figure 35. The microbenchmark performs \( k \) tasks; tasks 1 to \( k-1 \) are performed asynchronously and task 0 is performed serially. Under the work-first policy, the single worker execution incurs no context switch. Thus, the single worker execution time of the whole microbenchmark as a function of \( k \) for the work-first policy is

\[
t^w_{w_f}(k) = t_s(k) + t_{sf} + (k-1)t_{aw}
\]

where \( t_s(k) \) is the serial execution time of the whole microbenchmark as a function of \( k \). There is no extra synchronization cost \( (t_{ef}) \) at the end of the finish scope for single-worker work-first execution.

Under the help-first policy, tasks 1 to \( k-1 \) will be executed after a context switch and there is one non-trivial task synchronization at \( \text{end-finish} \) for \( k > 1 \). Thus

\[
t^h_{f}(k) = \begin{cases} t_s(k) + t_{sf} , & k = 1 \\ t_s(k) + t_{sf} + (k-1)(t_{ah} + t_{cs}) + t_{ef} , & k > 1 \end{cases}
\]

We assume every task in the microbenchmark shown in Figure 35 contains the same amount of work, \( t_0 \) (also called task granularity). The task granularity \( t_0 \) can be calculated as the slope of the serial execution \( t_s(k) \). Based on Equation 1 and 2, we have

\[
t_{sf} = t^w_{w_f}(1) - t_s = t^h_{f}(1) - t_s(1)
\]

\[
t_{aw} = \text{SLOPE}(k, t^w_{w_f}(k)) - t_0 \quad (k > 1)
\]

\[
t_{ah} + t_{cs} = \text{SLOPE}(k, t^h_{f}(k)) - t_0 \quad (k > 1)
\]

\[
t_{ef} = t^h_{f}(2) - t^h_{f}(1) - t_{aw} + t_{cs} - t_0
\]

We break down the single worker execution time \( t \) of a HJ program with a work-stealing scheduler into the following components: serial Java execution \( (t_s) \), \( \text{async} \) task spawns, context switches \( (t_{cs}) \) before starting a new task, \( \text{startFinish} \) \( (t_{sf}) \) and task synchronization at \( \text{endFinish} \). Depending on the scheduling policy, the overhead of asynchronous task spawns is denoted as \( t_{aw} \) for work-first task spawns or \( t_{ah} \) for help-first task spawns. The task synchronization at \( \text{endFinish} \) is either trivial or non-trivial. In the trivial case, all tasks created in the finish scope will be completed and the worker will just continue execution. In the non-trivial case, the current serial execution flow will be interrupted, and a context switch is performed before executing new tasks. We use \( t_{ef} \) to denote the overhead of non-trivial task synchronization. The overhead of the trivial case is considered to be included in \( t_{sf} \). A similar analysis can be performed for \( \text{get()} \) operations on future tasks, which are omitted for simplicity.

Consider the HJ microbenchmark shown in Figure 35. The microbenchmark performs \( k \) tasks; tasks 1 to \( k-1 \) are performed asynchronously and task 0 is performed serially. Under the work-first policy, the single worker execution incurs no context switch. Thus, the single worker execution time of the whole microbenchmark as a function of \( k \) for the work-first policy is

\[
t^w_{w_f}(k) = t_s(k) + t_{sf} + (k-1)t_{aw}
\]

where \( t_s(k) \) is the serial execution time of the whole microbenchmark as a function of \( k \). There is no extra synchronization cost \( (t_{ef}) \) at the end of the finish scope for single-worker work-first execution.

Under the help-first policy, tasks 1 to \( k-1 \) will be executed after a context switch and there is one non-trivial task synchronization at \( \text{end-finish} \) for \( k > 1 \). Thus

\[
t^h_{f}(k) = \begin{cases} t_s(k) + t_{sf} , & k = 1 \\ t_s(k) + t_{sf} + (k-1)(t_{ah} + t_{cs}) + t_{ef} , & k > 1 \end{cases}
\]

We assume every task in the microbenchmark shown in Figure 35 contains the same amount of work, \( t_0 \) (also called task granularity). The task granularity \( t_0 \) can be calculated as the slope of the serial execution \( t_s(k) \). Based on Equation 1 and 2, we have

\[
t_{sf} = t^w_{w_f}(1) - t_s = t^h_{f}(1) - t_s(1)
\]

\[
t_{aw} = \text{SLOPE}(k, t^w_{w_f}(k)) - t_0 \quad (k > 1)
\]

\[
t_{ah} + t_{cs} = \text{SLOPE}(k, t^h_{f}(k)) - t_0 \quad (k > 1)
\]

\[
t_{ef} = t^h_{f}(2) - t^h_{f}(1) - t_{aw} + t_{cs} - t_0
\]

Table 1 shows the execution time of the serial Java execution times and the single worker HJ execution time of the microbenchmark in Figure 35 for \( k = 1, 2, 4, 8, ..., 1024 \) on a Xeon SMP machine. A few data points are also provided for work-sharing \( (t^w_{w_f}(k)) \) and Java-thread implementations of \( \text{async} \) tasks.

We calculate \( t_0, t_{sf}, t_{aw}, t_{ah} + t_{cs} \) and \( t_{ef} \) from and get the following results from Table 1: \( t_0 \approx 0.1 \mu s \), or 417 cycles, \( t_{sf} \approx 0.1\mu s \) or 417 cycles, \( t_{aw} \approx 0.15\mu s \) or 625 cycles, \( t_{ah} + t_{cs} \approx 0.22\mu s \) or 917 cycles, \( t_{ef} \approx 2.11\mu s \) or 8800 cycles.
### A.2.2 Single-Worker Execution Times for Recursive Async example

Consider the HJ microbenchmark shown in Figure 36 and Figure 37. The code shown in Figure 36 uses a global finish to synchronize all tasks whereas each task in the code shown in Figure 37 waits for all child tasks. For fib(35), both versions spawns 29,860,703 tasks. The code shown in Figure 37 (version 2) will also create 14,930,351 finish instances. Using the earlier definitions and notations, the 1-worker execution times of the version shown in Figure 36 under the work-first and help-first policy are:

\[
t_{1wf} = t_s + t_{sf} + t_{aw} \times 29,860,703
\]

\[
t_{1hf} = t_s + t_{sf} + t_{ef} + (t_{ah} + t_{cs}) \times 29,860,703
\]

The 1-worker execution time of the code shown in Figure 37 under the work-first and help-first policy are:

\[
t_{2wf} = t_s + t_{sf} \times 14,930,351 + t_{aw} \times 29,860,703
\]

<tr>
<td>Code in Figure 37 (Version 2)</td>
<td>0.103</td>
<td>5.872</td>
<td>43.18</td>
</tr>
</tbody>
</table>

Figure 36: Version 1: Recursive microbenchmark with one global finish scope. Even though the method is called \( \text{fin()} \), it does not actually compute the Fibonacci sequence.
void fib (int n) {
    if (n<2) {
        // ... 
    } else {
        finish {
            async fib(n-1);
            async fib(n-2);
        }
    }
}

Figure 37: Version 2: Recursive microbenchmark in which every task waits for its child tasks. Even though the method is called fin(), it does not actually compute the Fibonacci sequence.

void fib (int n) {
    if (n<2) {
        // ... 
    } else if ( n > THRESHOLD) { // PARALLEL VERSION
        finish {
            async fib(n-1);
            async fib(n-2);
        }
    } else { // SEQUENTIAL VERSION
        fib(n-1); fib(n-2);
    }
}

Figure 38: Modified version of Figure 37 with threshold test

t^2_{hf} = t_s + (t_{sf} + t_{ef}) * 14,930,351 + (t_{ah} + t_{cs}) * 29,860,703

Table 2 shows the serial and 1-worker execution time of the code shown in Figure 36 and 37 under both policies. We compute t_{aw}, t_{ah} + t_{cs}, t_{sf} and t_{ef}, and get the following result: t_{aw} = 0.11\mu s (460 cycles), t_{ah} + t_{cs} = 0.23\mu s (960 cycles), t_{sf} = 0.17\mu s (709 cycles), t_{ef} = 2.26\mu s (9400 cycles). The results from both examples confirm that spawning and executing a task under the help-first policy (about 0.22-0.23 microseconds) is slower than the work-first policy (about 0.11-0.15 microseconds), and the context switch at the endFinish instruction is the most expensive operation (about 2.11-2.26 microseconds). The construction and destruction of a finish instance costs about 0.10-0.17 microseconds. We did not include results for work-sharing and Java threads for the recursive microbenchmarks because they would take too long to compute and, in some cases, may even run out of memory.

A.3 The “seq” clause for Async tasks

A very common way to reduce the large overheads seen in Table 2 is for the programmer to add a threshold test as shown in Figure 38. A THRESHOLD value of T implies that all calls to Fib() with parameters \leq T are implemented as sequential calls. However, one of the drawbacks of the approach in Figure 38 is that it violates the Don’t Repeat Yourself (DRY) principle of software engineering since the same work needs to be specified in the parallel and sequential versions. To avoid this problem, the HJ language supports a seq clause for an async statement with the following syntax and the semantics:

async seq(cond) <stmt> \equiv if (cond) <stmt> else async <stmt>
void fib (int n) {
    if (n<2) {
        . . .
    } else {
        finish {
            async seq(n <= THRESHOLD) fib(n-1);
            async seq(n <= THRESHOLD) fib(n-2);
        }
    }
}

Figure 39: Figure 38 rewritten with seq clause

The seq clause simplifies programmer-controlled serialization of task creation to deal with the overhead issue. However, the seq clause is restricted to cases when no blocking operation such as finish or get() is permitted inside <stmt>. The main benefit of the seq clause is that it removes the burden on the programmer to specify <stmt> twice with the accompanying software engineering hazard of ensuring that the two copies remain consistent. Figure 39 shows how the code in Figure 38 can be rewritten with the seq clause. In the future, the HJ system will explore approaches in which the compiler and/or runtime system can select the serialization condition automatically for any async statement. The seq clause is currently not supported for future async tasks.

Figure 40 compares the execution time of the work-first and help-first policies for Fib(45) using 64 workers and varying THRESHOLD from 5 to 20. As expected, the work-first policy (WS-WFP) significantly outperforms the help-first policy (WS-HFP) for smaller threshold values. This result re-establishes the fact that the work-first policy is well-suited for recursive parallel algorithms with abundant parallelism and small numbers of steals. However, if we increase the threshold to 20 (a value considered to be reasonable for Fib), the performance gap between WS-HFP and WS-WFP disappears.
